OBSERVATIONS IN CHINA AND THE TROPICS ON THE ARMY RATION AND THE POST EXCHANGE OR CANTEEN.*

BY MAJOR LOUIS LIVINGSTON SEAMAN, M. D., LL. B.,
NEW YORK,
LATE SURGEON FIRST U. S. VOLUNTEER ENGINEERS.

PEKING, United States Military Hospital No. 1, Camp Reilly, occupies one of the many compounds of the Temple of Agriculture, one of the most sacred and classic spots in the Celestial Empire. It is here that the "Son of Heaven," attended by high religious functionaries, comes annually in great pomp and splendor, on the Chinese New Year (corresponding with our 19th of February) to break the soil with his own hands, and to pray to the gods of air, and water, that sunshine and rain may bring bounteous crops to his land, and that prosperity and happiness may thereby come to his people. For reasons unnecessary to mention, for the first time in centuries, this beautiful and poetical ceremony was this year omitted. Occidental ideas in the way of punitive expeditions, revenge, lootings, ravishings, pillagings, the torch, drowning by thousands (twelve thousand innocents in one day driven into the Amur River at Blagoveshinski), being some of the methods now in vogue, for impressing a "higher civilization" on this unhappy land. But, as Kipling might say, "this is another story," only, it may be added, with patriotic pride, General Chaffee and the American forces were not participants in these acts of vandalism. They never forgot the laws of honorable warfare, and no deed can be attributed to them that will tarnish the bright escutcheon of this great Republic.

There is but one style of architecture in China, and its types never becomes monotonous because it is so artistically perfect. The larger temples, notably those in the forbidden City, the Ming Tombs, and those in the Compounds of "Agriculture" and "Heaven" are built on a raised dais of granite or marble masonry. They have neither basement nor gallery. The curved overhanging tiled roof is supported by almost windowless walls, save for here and there latticed openings and by massive columns of wood with heavy crossbeams. The splendor of the interior decorations is dazzling. Red in lacquer is the prevailing tint of the walls, while the monster crossbeams and ceiling are covered with innumerable dragons in gold and silver, on a frescoed background of green and blue. It is in such a building of splendid magnificence that the Medical staff of "The Chinese Relief Expedition" has quartered itself, and where, by invitation, I found myself most pleasantly billetted for nearly two months of the past winter. The floor space of the Temple being greater than was needed by the staff, one end was partitioned off as a dispensary, but the principal medical supplies were housed in a separate building. Flanking the main Temple on either side of the compound, are two others, one used as a recreation hall for the soldiers, the other as a hospital, with abundance of room for medical, surgical and venereal wards together with operating rooms and nurses' quarters. Both hospital corps men and trained female nurses are in attendance, and an extra diet kitchen supplies many delicacies. The service, under Major Ives, is most admirably conducted by Lieutenant Greenleaf and his able assistants, and the results obtained compare favorably with those of our best hospitals at home.

The "Report of Vital Statistics and Disease" for the week ending February 9, 1901, for the troops stationed at Peking, shows the mean strength of the command, including officers and men, of 1,559, with a total sick list of eighty, or .051 per cent.

The cases are of the nature usually found in a military hospital in America. Of the eighty, thirteen are diagnosed as suffering from "respiratory diseases," five from "accidents or injuries," four from "malarial fever," one from "typhoid," three from "digestive diseases," two unclassified, eleven as "circulatory," "muscular," "cutaneous," "special sense," "nervous" and other diseases, and forty-one as "venereal."

The climate of Peking in winter is cold, dry, and clear, ranging in January from 30 degrees Fahrenheit to ten below zero, without a storm during the month, except the wind, which often blows a gale, driving the dust in blinding clouds. Anyone who has ever experienced a Peking dust-storm will never want to repeat it; he will find that inhalations of ancestral dust are not conducive to healthful respiration. It is not surprising, therefore, that a rather large proportion of cases should be found under the heading of "respiratory diseases," especially when it is remembered that the troops, prior to their arrival in China, had served nearly two years in the tropical Philippines. They were the only ones of the Allied Army quartered in tents, (Sibley's) and pneumonia was the dreaded enemy. You will observe in the list enumerated there is but one case of typhoid fever. In this connection, it is interesting to note, that, on their arrival in China, it was the boast of the medical officers of the German army, that "typhus" fever (our typhoid or enteric) and "dysentery" were comparatively unknown visitors to their camps. Criticisms of the losses of the American army from these causes during the Spanish-American War, by our Teutonic colleagues, are not yet forgotten, and perhaps the lesson to the Americans has not been without benefit. At any rate, within two months of the arrival of the German Army in China, its hospitals contained over five hundred cases of typhoid fever, followed by an appalling list of fatalities, while the wards of the American hospitals were, and are still, singularly free. I found but one case either in Tien Tsin or Peking, and this man was a convalescent, while the number in the German wards still remains in the hundreds. The Americans have six water-distilling plants, while our neighbors have none, and therein undoubtedly lies one of the potent reasons for this remarkable contrast. Indeed, it may be added,

*Read at the Annual Meeting of the Association of Military Surgeons of the United States, held at St. Paul, Minn., June 1st.

the Americans had the only water-distilling plant in operation in Peking. Its capacity was so much greater than the requirements of the army, that two tons of the surplus water was donated by the hospital department to the Japanese army every day of the winter. The American Quartermaster (Major Byron) also cut and stored eight hundred tons of ice in Peking, at a cost of 1,252 Mexican dollars. It was the only ice ever housed in that ancient city, and curious bodies of natives used to gather around the camp to watch the novel work of the "foreign devils" and coolies.

It was indeed most gratifying, after spending a fair share of time during the past three years in the military hospitals of Porto Rico, Cuba and the Philippines, where a vast majority of the patients were suffering from preventable diseases—diseases resulting from blunders and ignorance—to make a tour through the wards at Camp Reilly and to note the distinctly different type of cases. The low percentage of all illnesses, except venereal, and especially the almost total absence of the class termed "digestive diseases," offer a startling contrast to conditions existing during the Spanish-American War in Porto Rico or Cuba. There I have seen as high as seventy-five per cent. of a command suffering from these diseases at one time. Or in the Philippines where, despite the constant depletion of the wards by death, or hospital ships, or United States Army transports, carrying from a hundred to five hundred invalided or convalescent men home per month, the percentage of these cases remains persistently high. One naturally looks sharply for the cause of this startling difference—a difference from 1-200 of one per cent. to seventy-five per cent. A glance at the men at their mess and a consideration of their environment discloses the secret. What appetites—what digestions! You would not believe these men were the emaciated, sallow-cheeked troops who came as the American army from the Philippines last summer. But they are. Here in this invigorating zero temperature, where animal heat is rapidly radiated and where nutritious foods, rich in fats and carbon, are requisite to maintain the body's temperature, the men show evidences of splendid health. It is not my purpose in the limited scope of this paper to review the merits of different foods (more than briefly to call attention to the dietetic value of sugar as a producer of energy) or the elaborate experiments of Mosso, who with the ergostat demonstrated that much less muscular deterioration occurred under a sugar diet, and that when muscles were fatigued and incapable of further work, sugar, a pure carbohydrate, most quickly restored their tone; or even to recall the elaborate tables of Ranke, who long ago demonstrated that four-fifths of the food consumed by the average laborer goes to the production of animal heat. In China, heat-producing foods were needed. Even our full army ration, the richest and most varied in the world, and the envy of every soldier of the allied armies in China, was not found sufficient to satisfy the cravings of the men. Repeatedly officers have told me their "company funds" were largely depleted by the constant demands of the men for extra allowances. Their appetites were enormous, their food was digested, assimilated and metabolized. The energy of their systems was not consumed in an effort to eliminate these heat-producing foods, as was the case when they were in the tropics, where they lived in an environment of heat, and where such foods were superfluous or inappropriate, and therefore were not digested or metabolized. Under these conditions such foods rapidly undergo decomposition in the intestinal tract and create toxins, which nature endeavors to eliminate as quickly as possible by establishing catarrhs and diarrhœa as the only method left to rid herself of such irritants.

And yet Congress has just decreed that no change shall be made in the United States army ration—that it shall remain practically the same at the Pole as at the equator. Fortunate, indeed, it is, that the soldier has learned, even though by bitter experience, that this is insanity. He sells his "sow-belly" and "salt-horse" when opportunity offers, and buys in exchange chicken or rice or fish or fruits and sweets, which are usually to be had in abundance in the tropics. The advocate of the present régime interrupts with: "He could always sell or commute his ration." Yes, provided he always had a market with him on his "hikes," but those who have served with him in a hostile country, or on the firing line, where he most needs a proper diet, know much better. The impartial and scientific observer sees in this answer only the beaurocrat's subterfuge, dictated by a spirit of resistance to change from established routine, and a lack of courage to shoulder responsibility for fatal blunders that have long crowded our tropic hospitals and made the mournful notes of "taps" so familiar in the land. Let it not be forgotten that in the Spanish-American War, the actual hostilities of which lasted only six weeks, there were fourteen fatalities from disease (practically all preventable) for one from bullets and wounds.

If any vindication were necessary for the theory for regulating the ration of an army to suit climatic conditions, unanswerable proof can be found in Peking in the study of the statistics of every company serving in the Chinese Expedition. At my earnest solicitation, Captain Anderson, commanding Company A, Ninth U. S. Infantry, obtained the following figures for me. His command, now numbering eighty-five, came from Manila to China with the first American troops landing at Taku last June. At that time, twenty-nine (or 33 per cent.) of the men were suffering from chronic diarrhœa contracted in the Philippines. On their arrival in China the combined weight of the company was 12,304 pounds. (I have the individual figures.) On February 15, 1901, these same men weighed 13,284, or an average gain of about thirteen and one-half pounds. There was not a case of so-called "digestive disease" in the company, nor a man in the hospital. On the contrary, to illustrate the state of the men's digestive ability, the captain adds:

"During the month of January, 1901, the following extra commissary supplies were used by my company: 3 bbls. (78 gals.) pickles, 240 cans cream, 240 lbs. oatmeal, 75 lbs. maccaroni, 60 lbs. cheese, 75 lbs. onions, 12 lbs. baking powder, 2 gals. syrup, 117 rations of bread, 127 lbs. beef. Total cost of extras $93.30 and paid from the company fund."

The reason for this remarkable difference lies in the changed climatic conditions, the extreme winter temperature of Pekin being fully 100° F. lower than that of Manila; in Peking this rich ration was requisite for the proper nourishment of the system.

As further bearing upon this point, let me submit the testimony of a witness, our American Consul at Formosa, whose opportunities for personal observation on this most important subject have rarely if ever been surpassed. His letter is better reading than medical statistics.

DEAR MAJOR SEAMAN. I have perused your very interesting pamphlet on the Army Ration, and the following personal observations may be of some interest to you. As you are aware I have had rather an unusual oportunity of confirming your statements on the subject of diet. The years 1893 and 1894, as a member of the Peary Arctic Expedition, I spent in North Greenland, within the Arctic Circle. On returning from this trip I departed almost immediately for Formosa, which is within the tropics, and called the most deadly climate in Asia, and the last six years have been spent in this island.

In North Greenland our supplies were naturally limited

to most portable foods, delicacies were left at home and we did not always have as much in quantity as we wished. It is not strange, therefore, that we, as young men, sometimes turned from our dry pemmican and biscuits to discuss the probable joys, from a culinary standpoint, awaiting us on our return to the States. You will doubtless surmise that oyster stews, roast turkeys, or pies "like mother used to make" were the subject of our discussion. These we could give warm welcome, still they were far from that glorious dish for which we all yearned and I might say, almost prayed—it was nothing more than a *side of bacon*. Not the streaky article marked "prime" but the kind that is practically solid fat and which the butcher in the temperate zone usually throws in the lard pot. We wished no side dishes, and even the cooking did not worry us much; in fact, I believe we would have preferred it merely warmed. On an occasional trip to the southern headquarters we were sometimes the recipients of a thin slice or so dealt out from our slender stock. And how good it was! There was nothing that could approach it. On one occasion I was fortunate, at least I looked upon it in that light, then, to obtain out of meal hours from the cook the outer skin or end piece of a side of bacon. I immediately sought the seclusion of my room, warmed it slightly over the flame of my candle, and then ate it with all the pleasure that a young boy obtains from his favorite confectionery.

Before our return from Greenland, I arranged with my room-mate, that on our arrival at St. Johns, the first port on our downward journey, we should go together to the leading grocery, which we had visited on our upward journey, and purchase a side of bacon. This we would take quietly to the hotel and for once have simply all the bacon we wished. Of course, on our actual arrival at St. Johns, the subject of bacon never entered our heads. We had entered the temperate zone, our systems ceased to call for fat, and we were prepared to give warm welcome to dishes of quite a different nature. This appetite for fat and fatty meats so keen in the far North, is merely Nature's call for help in repelling the almost overpowering cold, and if it is answered, there is but little fear of disease. There is probably not a healthier race on earth than the Eskimo of these regions, and our party suffered not the slightest indisposition while there. Yet the same diet in the tropics would be absolutely fatal.

In tropical Formosa, the idea of fat bacon was as repulsive as it was entrancing in the North. There, did I think of home delicacies, it was the splendid fruits, the strawberries, the luscious peaches that interested me. Nature had given me new tastes, new fancies, an appetite for something that would induce energy, without heat. If we were wise and obeyed her and left aside intoxicants and heavy fatty meats, we found our life a pleasant and not unhealthy one. And, although Formosa has the reputation of being the unhealthiest spot in Asia, I am convinced from my own experience of six years that one who is careful in one's diet, selecting only the foods which will tend to assist Nature rather than oppose it, will find life quite as healthy in Formosa as they will out of it, assuming of course, that they live in suitable quarters raised above the ground, and protect themselves against the midday sun when in the open.

In 1892, on my departure for Greenland, I weighed one hundred and forty-eight pounds; after six weeks of Arctic life on a suitable diet my weight increased to one hundred and ninety pounds. During several months' confinement with a frozen foot I lost heavily, and on my arrival in Formosa in 1894, weighed one hundred and fifty-five pounds. After a six-years' stay in the island during which I had not had a single sick day, I am now returning to my home land weighing one hundred and ninety-four pounds. The practical diet for a tropical country should, as you suggest, be light meats, chicken, fish, fruits, sugar, tea and rice which are to be found there in abundance. This is what I lived upon. During the two years I was attached to the Imperial Japanese Army in its campaign against the Chinese rebels in the island, I suffered as severe physical hardships as the average soldier finds in any military campaign in the tropics. By carefully obeying the dictates of Nature in the selection of foods, I have not—either in Greenland or Formosa—suffered *a single day from sickness*.

Yours truly,

JAMES W. DAVIDSON, F. R. G. S.,
U. S. Consul for Formosa.

Dated YOKOHAMA, Japan, March 21, 1901.

Could any testimony be more convincing? But of what value is the best evidence before a Court of Congress that would sell its birthright for a mess of pottage as was done by the last one, in its servile catering for votes, by submitting against its judgment, to the influence of a lot of fanatical and hysterical women, and abolishing the Army Post Exchange or "Canteen." As you well know, the overwhelming testimony of line and staff officers, men of probity and honor, total abstainers and others, was almost to a man, in favor of the retention of the Post Exchange. It is not my purpose to review the evidence on this subject; that was pretty thoroughly threshed out during the debate in Congress, but there was one very important factor that was entirely omitted in that discussion that may furnish a subject for reflection for those who were instrumental in bringing about this lamentable change. The enemies of the canteen seem to have forgotten that when men accustomed to the use of stimulants are deprived of them in one way, they will resort to other methods to obtain them. Less than five per cent. of the army are total abstainers. Citizenship is not forfeited by enlistment. Soldiers are not prisoners; they are well-paid men and have their pass days. The habits of the vast majority of them were formed *long* before their enlistment, and a large proportion of them belong to the class known as light drinkers. When the soldier cannot obtain a glass of beer or light wine at the post exchange in camp the first place he generally strikes for when on pass, is the nearest saloon, where in Porto Rico he is served with rum loaded with fusel oil; at home, vile doctored whiskey; in the Philippines, vino, a sort of wood alcohol, distilled from the nepa leaf; or in China the samshu, a product of rice—all rank poisons, one or two drinks of which "steals away his brains." Then follow excesses to which in his sober moments he would be the last to descend, insubordination, drunkenness, debauchery, or desertion.

The record of the Summary Court of the Twelfth U. S. Infantry shows that during February and March, 1900, at Paniqui, P. I., there were between seventy and ninety trials by court martial for each month. Four-fifths of the offenses were "intoxication from native vino." A post exchange was established in the latter part of March. Since then and until February, 1901, there were never more than twenty trials in any month, and one month the number was reduced to eight. The record shows no more than two cases of "vino intoxication" in any month. The company commander's report shows there are but eight total abstainers in the regiment.

In reviewing the report of vital statistics at Camp Reilly, you must have observed the high per centage of venereal diseases, over fifty per cent. of all patients under treatment being for this cause. It is to this distressing factor in connection with the subject of the canteen, that your attention is specially invited. Venereal disease always claims a large proportion of patients in a military hospital, but I have it on the authority of Lieut. Greenleaf and his assistant Dr. Lewis, than whom I have met no more conscientious officers in the Medical Department of the American Army, that since the abolition of the canteen the percentage of these cases has almost doubled. My own observations in other military hospitals tend to a similar conclusion. The men get their liquor away from the post, and leave the rum-hole for the brothel. When the canteen was maintained they drank less, were under better influences and returned sober and contented to their library and reading-room, or their other quarters. When the misguided enthusiasts of the W. C. T. U. stop to reflect that the result of their influence in inducing Congress to abolish the post exchange, has produced this enormous increase of wretchedness in the army hospitals, and made many a husband, father or lover the victim of a degrading disease, they may indulge in less self-

congratulation, and conclude to cease interfering with institutions about which they are so hopelessly ignorant. The post exchange was the most rational compromise that the ripe experience of the ablest officers of the army could devise; it was not abused in the camps; it has been the soldier's friend, often saving him from disgrace and disease worse than death, and the bill abolishing it should have been vetoed by a President who well knew its virtues. Some years ago the "Exeter Hall crowd" of England induced Parliament by methods similar to those used by the W. C. T. U., to abolish the Contagious Diseases Act in India, a law that had proved so effective in the elimination of these diseases that in 1884 they were comparatively unknown in the army there. To-day, owing to its abolition, there is no single cause so prolific in invaliding men home as this one. The Raines Law, another instance of meddlesome legislation, has been productive in spreading immorality to an extent heretofore unheard of in the greatest metropolis of this country, but there is no necessity of elaborating this subject to a medical audience. If the W. C. T. U. could be induced to direct its energies toward a co-operation with the medical associations of our country which are now making a study of the social evil and are endeavoring to bring about its segregation and limitation as far as possible within proper lines, it would *then* accomplish a great reform and prove itself a *real* benefactor to humanity.

Congress, however, when considering the repeal of the Anti-Canteen Act, as it must at its next session, will do well to remember that the abolition of the post exchange has not promoted temperance. On the contrary, it has decidedly promoted intemperance, insubordination, discontent, sullenness, disease, and desertion. It has embittered the men, and driven them to the very excesses sought to be abolished. You cannot legislate men to be virtuous or to be total abstainers, but you can, by judicious handling, promote chastity and temperance. The canteen fostered moderation. It led the hard drinker to less indulgence and removed the temptation which always clings to forbidden fruit. Its abolition angered the men. They felt it as an insult to their manhood, and a deprivation of their natural rights. They *will* drink if they wish, and they resent the attempt to prevent them. A glass or two of beer is not injurious to them, and they know it, and sneeringly criticise Congressmen—paid servants of the Government—who retain their well patronized cloakroom, with its private stock of good old whiskey, but who rob the soldiers—other paid servants of the same Government—of their right to take a glass of beer on their camp grounds in their well-disciplined and orderly canteens. And who will gainsay the justice of this conclusion?

The following resolutions, presented after a discussion of the paper, were unanimously adopted by the Association:

"WHEREAS, The Association of Military Surgeons of the United States, now in session at St. Paul, recognizes that the abolition of the army post exchange or canteen has resulted, and must inevitably result, in an increase of intemperance, insubordination, discontent, desertion and disease in the Army; Therefore, be it

"*Resolved*, That this body deplores the action of Congress in abolishing the said post exchange or canteen, and, in the interests of discipline, morality and sanitation, recommends its re-establishment at the earliest possible date."

At the meeting of the American Medical Association, also held at St. Paul, June 7th, the foregoing resolutions were unanimously endorsed.

THE PLACE OF CEREALS IN INFANT FEEDING.*

BY HENRY DWIGHT CHAPIN, M. D.,

NEW YORK.

A DISCUSSION of the propriety of using cereals in the feeding of infants may be approached from a theoretical or a practical and clinical standpoint. It is believed that the profession has recognized by long clinical experience that a certain judicious use of the cereals is frequently beneficial. On the theoretical side, it must be confessed that, at first sight, the employment of a material in a form not found in human milk may appear unwarranted to those who desire a strictly scientific reason for all procedures. A discussion of this question from the latter standpoint may be of interest if we bear in mind always the character and composition of cow's milk, with which the physician has to deal in his home modification to suit the infant's digestion.

The question then at issue is whether the use of cereals with cow's milk in infant feeding is unnecessary and unscientific. Unnecessary, because of the claim that cow's milk when diluted with water gives as fine, if not finer, curds than when diluted with cereal waters; unscientific, because nature is not being followed.[1]

The claim that cereal waters have no more effect on the curd of cow's milk than plain water has been abandoned, as it was based on the precipitation of casein with dilute acids and not upon its coagulation with rennet, which is what takes place in the infant's stomach.

When it comes to preparing cow's milk for the infant there arises the question, what constitutes following nature?

It is often claimed that the difference between woman's milk and cow's milk lies in the different percentages of fat, sugar, proteids, ash and water present, and that to follow nature the percentage of these ingredients of the infant's food should be made the same as those of average woman's milk and varied to suit the infant's digestion.

To determine the composition of a specimen of milk, resort to a chemical analysis is had. A portion of the milk is weighed and evaporated to dryness; the residue is weighed and called total solids;[2] the loss in weight is called water.[3] A part of the total solids is ignited and weighed as ash or salts.[2] What ether will extract from another part of the total solids is weighed and called fat.[2, 3] Another specimen of the milk is put through a complicated process to convert all the nitrogen present into the form of ammonia. The ammonia is distilled off and determined. The weight of the nitrogen in the ammonia is calculated and multiplied by 6.25 and called proteids, as 100 part of proteid bodies contain on an average sixteen per cent. of nitrogen which multiplied by 6.25 equals 100.[2, 3, 9]

The weights of the ash, ether extract, and nitrogen multiplied by 6.25 are added together and subtracted from the weight of the total solids, and the difference called sugar;[4] or a specimen of the milk is precipitated with various reagents, such as acid mercuric nitrate or copper sulphate, filtered, and the sugar in the filtrate determined by reduction of alkaline copper solution, or by the rotation of a ray of polarized light.[2, 3] When the sugar in woman's milk is determined by both reduction, of alkaline copper solution and rotation of a ray of polarized light, there is a difference in the quantity present, which indicates two sugars.[2] Direct separation of

*Read before the American Pediatric Society at Niagara Falls, May 28, 1901.

the sugar of cow's milk shows two carbohydrates to be present,[7] [8] but no method of quantitatively separating the sugar of milk in a state of purity is known.[3]

As the proteids of meat, milk, cheese, eggs, cereals, and even fertilizers are all determined by multiplying the weight of the nitrogen present by 6.25, or some other factor,[9] [10] and as this gives no clue to the properties of the proteids, chemists divide them into two great classes:[9]

1. Native proteids, those that can be separated from animal fluids and tissues by chemical means without losing their identity.

2. Modified proteids, those that are derived from native proteids by the action of heat in coagulating; by the action of acids or alkalies in forming acids or alkali albuminates, or by the action of proteolytic enzymes in forming albumoses and peptones.[9]

In milk we have to deal with native proteids and these are divided into groups according to their solubilities, as: albumins, soluble in water; globulins, insoluble in water but soluble in dilute neutral salt solutions or weak acid or alkali solutions; and neucleo-albumins which are soluble in dilute alkali solutions. There are no sharply dividing lines between these groups. The neucleo-albumins differ from the albumins and globulins in containing phosphorous. There are a number of kinds of albumins, globulins and neucleo-albumins.[9]

In both woman's and cow's milk are found albumin, globulin, and neucleo-albumin (casein). The albumin in woman's milk forms from one-third (Richmond) to two-thirds (Kœnig) of the total proteids, while in cow's milk the neucleo-albumin (casein) forms about four-fifths of the total proteids. There seem to be some soluble proteids similar to albumin in every kind of milk that has been examined.

When the nitrogen of the albumin, globulin, and neucleo-albumin (casein) of milk is determined separately, there is found to be less nitrogen than when the nitrogen is determined directly from the milk; one-eleventh of the nitrogen of woman's milk and one-sixteenth of the nitrogen of cow's milk is thus unaccounted for.[9]

Backhaus and W. Cronheim recently reported the analyses of twelve samples of human milk. In agreement with the results of Camerer and Söldner, "it was found that there was a discrepancy between the total solids and the sum of the constitutents of the total solids, as determined separately, amounting to from 0.68 to 2.045 per cent. This is held to represent an unknown constitutent which passes into the filtrate when the albuminoids are precipitated with alcohol."[5]

When milk is taken into the stomach it is first clotted by the rennet which produces a chemical change in the casein. A clotted jelly which encloses the fat is formed from cow's milk, and a soluble proteid known as "whey proteid,"[9] similar to an albumose is split off from the casein. A clear fluid, known as whey exudes from the curds and contains the "whey proteid," albumin, globulin, and sugars of the milk. To quote J. Reynolds Green,[10] "When casein either in milk, or in solution in dilute alkalies, is acted upon by rennet in the presence of a small quantity of calcium phosphate, it is at once chemically altered. It gives rise to the formation of a body which has been named tyrein, which is the proteid constituent of the clot. When the whey has separated out, it is found to contain a by-product having properties resembling those of a soluble albumin, except that it is not made insoluble by boiling. It is consequently distinct from the serum albumin, or lactalbumin, present in normal milk. The formation of this by-product, when solutions of pure casein are treated with rennet, shows that it results from the alteration of the casein. The clotting of milk by rennet is consequently not to be confused with the precipitation of casein by acid."

The curding process consists essentially of a separation of the fat and casein from the easily absorbable proteids and carbohydrates.

Albumin, globulin and albumose can be absorbed with little digestive effort. Neucleo-albumin (casein) must be peptonized before absorption. All proteids are in some unknown way changed before passing into the blood, for even peptone is excreted by the kidneys when injected into the blood.[11]

During digestion there is an increased elimination of nitrogen which is proportional to the intensity of digestive work, and an increase of about fifteen per cent. in the quantity of oxygen consumed and a larger increase in quantity of carbon dioxide thrown off.[12] This shows an immediate demand for proteids and carbohydrates at the beginning of a meal; it has just been shown that the first step in the digestion of milk is a separation of easily absorbable proteids and carbohydrates (sugars) from the casein and fat which require digestion as they are left in a semi-solid state.

The character of the curd that is formed in the stomach seems to depend on the milk that is used.[2] [10]

The milk of the cow, goat, sheep and buffalo, which are ruminants, shows a wonderfully close resemblance in chemical composition, and the curds formed with rennet are solid.

The milk of the mare, mule,* and ass, which are not ruminants, also shows close resemblance in chemical composition, but is quite different from that of ruminants, and the curds formed with rennet are soft and flocculent. The milk of the cat and dog, carnivorous animals, is very much alike in composition, but decidedly different from that of either class of herbivorous animals. Nothing is known about the curding properties.

Among the herbivoræ, at least, the rule seems to be, animals that ruminate, furnish their young with milk that curds in solid lumps, and animals that chew their food before swallowing it, furnish their young with milk that curds in loose flakes. The human stomach receives food in a finely divided state and woman's milk curds in loose flakes.

A glance at the following table constructed from analyses in Richmond's "Dairy Chemistry"[2] will also show that the milks that form solid curds with rennet are furnished by animals whose normal digestion is prolonged and whose intestinal canals are relatively very much longer than those of animals whose milk forms soft flaky curds, and that carnivorous animals, whose intestines are relatively very short, furnish milk rich in proteids, half of which are readily absorbable. The gastric juice of a dog will digest in the same time four times as much cooked albumin as that of a sheep.[13]

It is also interesting to note the rapid growth of animals whose milk is rich in proteids, much of which is present in a soluble form.

	Water.	Fat.	Sug.	Cas'n.	Alb'n	Ash.	Curds	12 Ratio of intestine to body length	13 Doubles its weight in
Carnivorous:									
Cat,	81.63	3.33	4.91	3.12	5.96	.58	?	4 to 1	9½ days.
Dog,	75.44	9.57	3.09	6.10	5.05	.75	?	6 to 1	8 days.
Ruminant:									
Ewe,	79.46	8.63	4.28	5.23	1.43	.90	Solid,	27 to 1	10 days.
Goat,	86.04	4.63	4.22	3.49	.14	.76	Solid,	27 to 1	19 days.
Buffalo,	82.63	7.61	4.72	3.54	.60	.90	Solid,	.....	.....
Cow,	87.10	3.90	4.75	3.00	.40	.75	Solid,	20 to 1	47 days.
Non-Ruminant:									
Mare,	89.80	1.17	6.89		1.84	.30	Flocln't,	12 to 1	60 days:
Mule,	91.50	1.59	4.80		1.64	.38	Flocln't,	11 to 1	....
Ass,	90.12	1.26	6.50	1.32	.34	.46	Flocln't,	11 to 1	....
Human:									
Woman,	88.2	3.30	6.80	1.00		.50	.20 Flocln't.	6 to 1	180 days.

*It may be of interest to note that the female mule will sometimes reproduce by union with either the horse or the ass.

A table essentially the same was also constructed from analyses by Koenig. The percentages were slightly different, but not more so than would be accounted for by variations in milk.

During the first days of life, all young suckling animals are furnished colostrum, which is rich in proteids consisting largely of albumin and globulin,[2, 5, 6, 14] the most easily absorbable forms of native proteids, and sugar, which, in the case of the cow, is largely dextrose,[2,5,6,14] the sugar found in the blood. Colostrum will hardly curdle with rennet,[2,6,14] and the stomach of a calf under three days old furnishes a very weak rennet.

The change from colostrum to milk, which takes place during the first week or two after birth, consists of a reduction of the easily absorbable proteids and sugar, until in normal cow's milk, the easily absorbable proteid is less than the casein,[2] which calls forth considerable digestive effort. All normal milk contains a portion of the proteids in a form that is not acted upon by rennet. Not much is known about the sugars, as they are estimated together, and then not directly.[2]

When mixed solid food is taken by a child or an adult, it must be chewed and mixed with saliva, by which some of the starch is converted into dextrin and maltose, which are easily absorbed.[9] Thus in every stage of life the food is adapted to the condition of the animal. At birth when the digestive process is being set up, the food requires little digestion; as the animal's digestive apparatus commences to work, the food in the stomach gradually changes from a fluid to a semi-solid state peculiar to each class of animals. The increased demand for proteids and carbohydrates during digestion is met by a separation of the soluble proteids and carbohydrates as soon as the milk is swallowed, and when solid food is taken, a supply of soluble absorbable carbohydrates is produced by the action of saliva on the starch. Furthermore, the secretion of all the digestive juices is promoted by the absorption of nutriment at the beginning of a meal.[10]

When cow's milk diluted with water is given to an infant the quantity of readily absorbable food is reduced to almost nothing, and the proteids will form a solid curd if the conditions are right. In practice, with all the advantages of a laboratory and an almost perfect milk supply, it is found necessary to begin an infant on proteids one-eighth to one-fourth of the quantity found in woman's colostrum and milk, and gradually increase the quantity as the infant can digest them. The one element that is kept up is sugar. This practice conforms to observations that have shown that an amount of ingested proteids smaller than the amount that is being excreted may enable an animal to show a gain in proteids if additional carbohydrates are furnished at the same time, and that increased quantities of carbohydrates in the food decrease the proteid metabolism more regularly and constantly than increased quantities of fat.[9]

The practice of the advocates of percentage feeding shows that an adjustment of the percentages of fat (ether extract), proteid (nitrogen X 6.25), and sugar of cow's milk, to equal those of woman's milk does not enable them to strictly follow nature in percentages, for nature most decidedly protests when the same percentage of proteids of cow's milk as is found in woman's milk is given to a young infant; this shows that percentage feeding simply records the quantities of these ingredients of *cow's milk* a particular infant is able to digest. Good clinical results have been obtained, and so they have been with other methods, but the claim that in this way only nature is being followed is not well founded. The introduction of system into infant feeding has been a great advance and has come to stay, but it has emphasized the fact that changing percentages does not change cow's milk into woman's milk.

Practice has shown that each infant is a law unto itself, no matter what method of feeding is employed. Now, if nature is to be followed, the infant's food should curd in flocks or loose masses and there should be a moderate supply of easily absorbable food separated at the time the curds form. As sugars have such a sparing effect on proteids they can be used to replace part of the soluble proteid which is reduced in quantity by dilution of cow's milk.

When sugars of milk are examined directly and not determined by "difference," sugar of woman's milk is found to be different from sugar of cow's milk[2] and cow's milk is found to contain two carbohydrates, one of which Béchamp considers to be dextrin[7]. Chemistry shows cane sugar, milk sugar and maltose to have the same composition ($C_{12}H_{22}O_{11}$) and all three rotate a ray of polarized light in the same direction (Cane Sugar, $+66.5°$, Milk Sugar, $+52.5°$, Maltose, $+137°$). Cane sugar and milk sugar when injected into the blood are excreted unchanged. Moderate quantities of dextrin and maltose when injected into the blood are retained.[9,10] The first products of digestion in the adult are dextrin and maltose, and these have been proved to be absorbed from the stomach and to provoke the secretion of all the digestive juices.[10] Even young infants can digest quantities of small starch.

In 1893 it was discovered that there were two enzymes, diastase and glucase, in the blood serum and lymph, one of which converted glycogen, which is the form in which carbohydrates are stored in the liver, into dextrin and maltose, and the other which converted maltose into dextrose, which is the sugar found in the blood, and which is converted again into glycogen in the muscles and cells of even the embryo;[9] so it can not be claimed that in the addition of small quantities of starch, dextrin or maltose to cow's milk elements are added than an infant is unprepared to care for.

To break up the curd of cow's milk and furnish a small quantity of easily absorbable food, cereal gruels, in which the starch has been converted into dextrin and maltose, are the most practical and desirable agents. It has been denied that cereals or any kind of mechanical attenuant had any effect on the curd of cow's milk,[11,15] but this was found to be based on a mistaken conception of the curding properties of milk. Recently it has been admitted that cereals gave the finest curds of any diluent,[11,15,16] but it was claimed that all the effect of the cereal is lost when the starch is digested, especially if the digestive ferment is active.[16] How much effect a digested gruel has on the curding of milk depends on the strength of the gruel and the dilution of the milk. The very best effect as far as digestive effort is concerned is obtained when the starch is completely gotten into soluble forms so that the particles of proteids and cellulose of the cereals are free. Any one who has seen junket made has noticed how the curd shrinks away from the dish. The curd of cow's milk which has been diluted with thoroughly digested gruel shrinks away from each little particle of cellulose and proteid of the cereal, and allows a rapid exudation of the soluble, easily absorbable portion of the food consisting of albumin, globulin, "whey proteid," dextrin, maltose, and milk sugar. Sometimes the curds may hold their form, but they are spongy and soft, never leathery, and break apart on slight agitation.

To find what strength of the digested gruel was needed to prevent the formation of leathery curds,

three heaping tablespoonsful of wheat flour, weighing 1,562 grains, were cooked in a double boiler for two hours with three pints of water in my kitchen; as it could be done in any household. This gruel was cooled so that it could be tasted (130° F.), and one teaspoonful of cereo, a glycerite of diastase, was added. At the end of ten minutes iodine failed to show starch.

A quart of milk was obtained and tested for fat and showed four per cent. It was amphoteric to litmus paper, but showed 0.15 per cent. acidity to phenolphthalein. The acidity of milk is never determined directly,[2] but by neutralizing with alkali, the end of the reaction being indicated by the change of some color indicator. Milk is nearly twice as acid to phenolphthalein as to litmus.[2]

One part of this milk was diluted with an equal quantity of water, another part with one and one-half per cent. starch jelly and another with the digested gruel; 0.15 per cent. HCl and some liquid rennet were added to each.

The artificial curding of milk with rennet is dependent on the temperature, acidity of the milk and the strength of the rennet;[6,7,11,14] whether the acid and the rennet are added together or separately, and if separately which first.[5] The curd produced when rennet is first added is tougher than when acid is first added, as the rennet has then more opportunity to come in contact with all the casein, for the acid has a tendency to throw the casein out of solution before the rennet can come in contact with it.[5]

In making these tests it was desired to make the curds as tough and leathery as possible, so the rennet was first added to the cold diluted milk and the acid afterward. The mixtures were then warmed without agitation and allowed to shrink until the curd of the specimen diluted with water could be dropped on the floor or tossed like a ball without breaking. This was the severest test that could be devised.

The curds of the specimen prepared with one and one-half per cent. starch jelly and the digested gruel were very much alike in texture. Neither was tough and leathery. This difference was noticed; in one the curds of the milk were coated with starch, in the other the curds were thoroughly exposed.

It is not necessary to use a digested gruel stronger than one heaping tablespoonful of flour to the pint for any dilution of milk.

If when modified milk disagreed all milk was cut off for a few feedings, and then a new beginning made, a great deal less trouble would be experienced than by attempting to shift percentages slightly. It might be found that the milk itself was at fault. Something has to be fed when milk disagrees. The question is, shall the physician furnish this substitute or turn the baby over to the manufacturers of proprietary infant foods?

There is no form of nourishment so easily borne as predigested cereal gruels, and when properly used these are of great benefit, even when the infant is breast-fed.

A glance over the standard text-books and recent articles [15]—[22] will show how often the cereals in one form or another are called into use; almost always when milk must be withheld; and it is just at these times that infant foods, which are made principally of cereals, are used.

If instead of claiming that it is unscientific to give a baby anything but milk, the great advantage of temporarily withholding milk when it disagrees, and feeding cereal gruels instead of proprietary foods was taught, and then to return to milk feedings by gradually adding milk to these gruels there would be less recourse to proprietary foods and more practitioners would learn to become scientific modifiers of milk. This method can be followed anywhere and in no way interferes with the principle of shifting the percentages of fat, sugar or proteids to suit the infant's digestion. In fact, this is exactly what should be done in every case.

It would seem that by beginning with a predigested cereal and adding milk to this, nature would be pretty closely followed in furnishing part of the food in a readily absorbable condition and in rendering the remaining portion soft and flocculent. This is practical and seems more scientific than making the standard what ether will extract from the food, the amount of nitrogen it contains, and the rotation of a ray of light or the reduction of alkaline copper solution it produces.

The conclusions are, that chemical analyses of milk are not the only scientific bases of comparison; that nature adapts an animal's milk food to its digestive system, and that cow's milk and woman's milk were intended for different digestive systems; that as cow's milk forms solid curds and woman's milk flocculent curds, the curd of cow's milk intended for an infant should be broken up mechanically; that as cereal gruels mechanically break up the curds of cow's milk, and as infants are able to utilize them, their use is rational.

It is often preferable to make the standard diluent of digested gruels, as they not only break up the curds but expose a surface of milk proteids and not starch, and furnish a certain amount of nourishment that is immediately available for carrying on the work of digestion, taking the place of part of the soluble proteids, and also form a satisfactory substitute for milk when it must be withheld for a few feedings. A great variety of food can be supplied an infant by means of digested gruels at a trifling expense, and the tendency is always to get back to milk feedings and not to keep on indefinitely with a diet of carbohydrates, as when most infant foods are used.

THE VALUE OF LOCAL SANATORIA IN THE COMBAT OF TUBERCULOSIS IN LARGE CENTERS OF POPULATION.*

BY S. A. KNOPF, M.D.,

NEW YORK

MR. CHAIRMAN and MEMBERS of the LAENNEC SOCIETY:—Let me congratulate you on the choice of the name which you have given to your society. The name of Laennec has always been to me an inspiration in my work on tuberculosis. We are indebted to this great man for having simplified the study of the pathology of tuberculosis, demonstrating once for all time the pathological unity of all tuberculous lesions. In clinical work René Théophile Laennec taught us the use of the stethoscope and how to auscultate the chest. To these two great achievements in phthisiology he added a third by demonstrating the curability of pulmonary tuberculosis. A better name you could therefore not have chosen for your society. The latter distinguishes itself from other organizations for the prevention of tuberculosis by doing work which not only consists in diffusing in the profession and the public a knowledge of the disease, but also in systematizing and stimulating the work on tuberculosis in the hospital, and educating its members. I cannot conceive of a more glorious mission for medical students, young physicians, and teachers of medicine. By such work you are helpful in solving one of the most difficult of the medical and social problems of our times. You are doing the work of the true physician, who should not only be a healer but also a teacher.

While you have not organized for any other purpose than to be helpful to others, I hope, nevertheless, that the public, the commonwealth, the municipality, and the State authorities, whom you are trying to benefit, will meet you in your noble endeavors and be helpful to you. The public at large and the families in which you are to practice should learn to appreciate, through your present work, the value of a family physician as one who is called not only to treat but also to prevent disease. By the periodical examination of all the members of families in your charge you will not only discover pulmonary tuberculosis in its very earliest stages, but by your knowledge of the constitutions of the various members of the family you will be able to institute proper prophylactic treatment and through timely judicious advice save many individuals from ever becoming tuberculous.

It has always seemed to me that the proper solution of the tuberculosis problem will also more nearly solve the problem of the family physician than anything else. I cherish the hope that the American family physician of the Twentieth Century will be duly appreciated, and that families will learn that, whether there is sickness among their members or not, to be visited by a skilful physician, trained in sanitary and preventive medicine, would be most advantageous to their welfare. Such families should realize that the timely advice given to them to prevent disease is worth a good consultation fee. The family physician should be paid, and well paid, for his services in protecting a family from disease by teaching them the proper way of living and the use of sanitary precautions.

The authorities—State and municipal—should facilitate your work by placing at your disposal the means to establish a sufficient number of institutions, sanatoria and especial hospitals, to accommodate the great number of consumptive poor. The philanthropists should, in the same way, recognize your services by being helpful to you in your care of tuberculous sufferers without means.

This brings me to the main subject of my talk. I desire, if possible, to emphasize what has been already better said so many times and by others more familiar with your local conditions than I am, regarding the value of local sanatoria in the combat against tuberculosis in the large centers of population.

The first question which one might be expected to answer in relation to this subject is "What is a local sanatorium for the consumptive poor?" This question might best be answered by first stating what it is not. A local sanatorium for consumptives is not a sanitarium or health resort, nor an ordinary hospital or home. Such a sanatorium is not like a general hospital inasmuch as it treats only patients suffering from tuberculous diseases, and the equipments of the institution are particularly suited to the open-air, hygienic, and dietetic treatment of consumptives. A sanatorium for the treatment of consumptives is not a home managed by the gentle hand of a minister, Sister of Charity, or matron, but an institution where patients are treated, not kept. There the trained physician not only carries out the most approved hygienic and dietetic treatment of tuberculosis, but infection of other persons through the ignorance or carelessness of patients is made impossible by the proper training of the invalids and the constant medical supervision on the part of the physician and his assistants. To make the distinction between a home and sanatorium still clearer I may say that a properly conducted sanatorium for consumptives is not a danger to the neighborhood, but a blessing. In some German villages where sanatoria for consumptives have been in operation for over thirty years, the mortality from tuberculosis has actually decreased one-third among the villagers since the establishment of the institutions. The reduction in the mortality from tuberculosis among the villagers is to be explained by their involuntary imitation of the cleanliness and sanitary precautions practiced in the institutions in their midst. On the other hand, in certain climatic resorts where patients live in homes or in hotels and boarding houses, the mortality from tuberculosis has been on the increase.

Instead of calling such an institution as described above a sanitarium, from *sanitas*, health, I prefer the word sanatorium, from *sanare*, to heal, because it is a better equivalent to the German "Heilanstalt," the name given to the first institution of this kind by Hermann Brehmer, the principal founder of modern phthisio-therapy. A local sanatorium, or closed establishment, distinguishes itself from a health resort in many ways. Consumptives are sent to health resorts for supposed specific climatic advantages, and there the patients are under no restraint but can do precisely as they please. The local sanatorium, on the other hand, is situated near some large center of population with a view of curing the tuberculous patients in the same or nearly the same climate in which he will have to live and labor after his restoration to health.

The next question which the layman or physician, not familiar with modern phthisio-therapy, may ask is: "Can good results be obtained under such climatic conditions as are found near large centers of population?" I am the last one to deny the value of climatic conditions, such as high elevation, insolation, pine forests, and protection from cold winds, but I desire to emphasize that even the ideal climate for a consumptive, if there is such, cannot be considered as anything but a valuable adjuvant in the hygienic and dietetic treatment. If I should have to

*An address delivered before the Laennec Society of Johns Hopkins Hospital, Baltimore, May 25, 1901.

choose between sending a patient to such an ideal climate there to do as he pleases, or having him here in Baltimore in the hands of a conscientious practitioner who would carry out the most approved hygienic and dietetic treatment, I would certainly take the latter course, for I think the patient's chances for recovery would be greater in remaining here than in going away. Furthermore, I think there is hardly any city in the United States which has not within a radius of from one to three hours by rail some particularly healthy spot, with dry porous soil, free from dust, traffic, and miasmatic conditions, with relatively pure air, where such a sanatorium for consumptives could be built.

That the results obtained in such local sanatoria are remarkably good has been demonstrated in our own country by the Sharon Sanatorium near Boston and the Chestnut Hill Hospital near Philadelphia. There is one more reason why I favor local sanatoria for the treatment of consumptives coming from the poorer classes. To send a consumptive away where he can see his family and friends only at great intervals or not at all, because the visit to the institution is too expensive an affair, is always a risky undertaking. The consumptive suffers perhaps more than any other patient from that little recognized, but often very painful disease, homesickness, scientifically called nostalgia. By enabling our consumptive patient, separated from his family all the week, to look forward to Sunday when he can see his loved ones, we render him happy and hopeful. On the other hand, by removing him many miles from his home and former associates we only add another item to his sufferings. All those who have studied the psychic condition of the consumptive will agree with me how essential it is for his recovery to keep him hopeful and in good spirits.

The next question to be discussed would be: "Is there truly a need for such sanatoria?" As examples, I will only mention two cities, New York and Baltimore. In New York, we have about 40,000 consumptives of whom, I venture to say, more than half must be considered as belonging to the poor and living in tenement houses. There are in the city of New York only two or three hospitals which take chronic tuberculous patients, accommodating about six hundred. According to information, for which I am indebted to your distinguished chairman, Prof. Osler, you have in your own city about 10,000 consumptive poor, of whom at least 6,000 are dependent upon public aid. The one hospital in Baltimore which admits chronic consumptives, accommodates about twenty-two of this class of patients. This must seem to us all very, very little help in presence of such misery. What becomes of the consumptive who is too poor to pay a regular physician and too weak to go to the dispensary, very few people know, with the exception of the physician who may practice in the quarters of the poor or the visitors of the charitable organizations whose calling brings them in contact with these unfortunate sufferers. It is a strange but significant fact that for the poor consumptive, who is in the greatest need of municipal or State help, the least is done. We have veritable palaces for the insane, excellent institutions for the epileptics, even institutions for the cure of inebriates, but nothing for either the curable or incurable consumptive poor.

We hear daily of the great gifts our philanthropists bestow upon general hospitals, or for the creation of libraries, but donations for the prevention or cure of consumptives are of the rarest occurrence. I can only account for this indifference on the part of our philanthropists by the fact that they have not thus far a true idea of the suffering of a poor consumptive. I have often wished that I could take some of our Carnegies, Rockefellers, or Vanderbilts into the home of one of our New York tenement dwellers who is dying the lingering death of a consumptive. These philanthropists would appreciate better in one-half hour of actual inspection what misery there is in this than would be possible for them to gather from all the descriptions which could be presented to them. They could take in at a glance the life history of an honest laborer, who became tuberculous, but worked until the day when he was brought home in a fainting condition, never to leave his bed again. They would appreciate the devotion of a wife who took upon herself the burden of the support of the family from that day on. They would soon realize that the unhealthy appearance of the children which seems to stamp them too as candidates for consumption is due to the lack of air and sunlight in the badly ventilated, dark and dreary tenement home and to the evident underfeeding of these little ones.

Yet how little would have been needed to prevent all this misery! Six to nine months proper treatment in a well conducted sanatorium would probably have sufficed to cure the tuberculous laborer had he known where to go to at the first onset of the disease. But how relatively few city governments, how few philanthropists, take any interest in this great tuberculosis problem, which is just as much a social as it is a medical one. By a combined action of the statesmen, the city fathers and the philanthropists it would be easy, if not to stamp out entirely, at least to reduce the morbidity and the mortality of this disease in a very remarkable degree.

Statesmen and the philanthropists could work for the prevention of this disease in three ways: first, by erecting model tenement houses where light and air would be plenty and where the laboring man could enjoy the pleasures of home life and find that comfort and cheerfulness, the lack of which, in the majority of the tenement houses, so often drives him to the corner saloon. Secondly, by helping to erect local sanatoria for the treatment of tuberculous diseases in all stages, in children as well as in adults. Thirdly, by judiciously exercised charity they could take upon themselves the support of the family which through the sojourn of the breadwinner in the sanatorium is temporily deprived of the necessities of life. Underfeeding of the children, because of the sickness of their father, could thus not happen, nor would the wife be obliged to leave the children alone and without care, because it would not be necessary for her to become the breadwinner.

Such conditions as I have pictured of the consumptive poor in New York exist also here in Baltimore and in many other of our large American cities. I believe a strong appeal to the philanthropists of your city to combine with your city or State government to remedy these conditions as far as possible would be timely. By having sufficient suitable hospital and sanatorium accommodation for the consumptive poor of your city, you will not only cure a large number of tuberculous patients and make of them useful citizens and breadwinners for their families, but you will suppress countless centers of infection, and thus do a curative and preventive work at the same time. Impress upon those to whom you are to appeal for help the following maxims: Tuberculosis, particularly in its pulmonary form, is a highly communicable disease. The patient not treated or educated in regard to the infectious nature of his sputum, is a danger to the community in which he lives, but particularly to those with whom he may come in close contact. The badly housed, the underfed, the overworked, or those who are

enfeebled through excesses or disease soonest fall victims to the tubercle bacillus. According to the estimate of Prof. Osler, through whose courtesy I am privileged to address you this evening, there are over 1,250,000 cases of consumption in the United States all the time, of which I venture to say, a large majority are doomed to an untimely death. Yet tuberculosis is a preventable disease, and consumption and many of its other forms are in most instances curable. Consumption is a disease of the majority, and therefore the majority and not the minority should be taken care of. The consumptive poor taken care of in time, treated and cured, will in the end cost the community less than the consumptive not taken care of in time but allowed to die in his home or the almshouse.

Consumption can be prevented by proper sanitation, training, and education; it can be cured in nearly all climes by proper hygienic and dietetic treatment, under constant medical supervision, at home or in a sanatorium. In short, to combat tuberculosis we must be permeated with the thought that it is a parasitic, but a preventable and curable disease, and that everyone, rich and poor, the physician and the layman, must do his duty in the combat of the "great white plague." Let the words of the immortal Pasteur be inscribed on the flag of this American Anti-Tuberculosis Crusade: "It is in the power of man to cause all parasitic diseases to disappear from the world."

16 West Ninety-fifth Street.

OBSERVATIONS AND REMARKS ON REMOVAL OF THE GASSERIAN GANGLION IN THE CADAVER.*

By ROBT. F. AMYX, M.D.,
ASSISTANT SUPERINTENDENT, ST. LOUIS CITY HOSPITAL.

The above subject will not need any introduction. The recent surgical literature has contributed largely in bringing it before the profession; the various methods which have been practised and the improvement of the methods now in vogue have been discussed in all their phases. The improvement in the present technique is largely due to careful observation of the anatomical relations of the Gasserian ganglion to the surrounding structures, which heretofore were only generally considered. To-day every structure has been segregated and its importance properly appreciated. This and the improvements in instruments, which are made especially for and adapted to the region of the Gasserian ganglion, have together simplified an operation that many surgeons have considered so formidable that they have discarded it as a procedure for the relief of trifacial neuralgia. Happily this uncertain state of affairs has been changed to one of confidence, and at the present time removal of the Gasserian ganglion is being performed by many surgeons throughout Europe and this country, with a degree of success which recommends it as a rational procedure and one which affords the only relief for trifacial neuralgia.

Before describing the technique of the operation, there are three considerations which must be taken into account. First, the physical type of the individual, that is, in reference to the bony structure and shape of the skull. My observation on something over fifty skulls, on which I have practised the operation, have led me to make the following conclusion: In skulls having a great transverse width just in front of the ears, a width consisting of the skull alone, without any additional muscles or the zygomatic arch, the floor of the middle fossa does not have marked bony prominences arising from it; while in heads not having a great transverse diameter between the ears, but whose external bony prominences are large and sharply marked, the floor of the middle fossa is studded with large bony eminences, which are situated external to the foramina ovale and rotundum. We often encounter skulls having a combination of these two types. A knowledge of the above facts will give us some kind of information of the condition that we are to meet with in the middle fossa. The wider head gives a smooth floor to work over in order to dissect the ganglion, but it has the disadvantage of a greater distance to the site of the ganglion, a condition which usually lessens the amount of light that can be thrown into the aperture. On the other hand, the narrow head offers a shorter distance to the ganglion, but usually has the disadvantage of having large bony prominences, which obstruct the view to the foramen ovale and sometimes to the foramen rotundum, so that the removal of the ganglion is laborious and oftentimes impossible, until the prominences of bone are removed from the floor of the middle fossa. Skulls of the third type are those having a wide transverse diameter as well as marked bony prominences, and offer a combination of difficulties. In the latter type we find the greater distance to the ganglion as well as the large bony elevations which arise from the floor of the middle fossa, and there is needed a greater elevation of the brain in order to throw sufficient light on the site of the ganglion. Whenever we encounter this type of skull, the distance can be shortened materially by opening forward toward the foramen rotundum, so that we can approach to within one-half inch of the second root of the ganglion. In these cases a larger hole should be made in the skull, so that a better elevation of the brain can be made in order to secure more light. In those skulls having large bony prominences the manner of chiseling these prominences from the floor of the middle fossa is of great importance. It is best done by chiseling from behind forward, this direction being away from the foramen spinosum, so that the middle meningeal artery is not cut, an accident which is liable to happen if the direction of the chiseling is backward.

The second consideration is the attachment of the dura mater to the ganglion and surrounding structures. The dura mater in the middle fossa as it passes forward divides, sending a prolongation downward and forward beneath the Gasserian ganglion, and firmly attached to the bone beneath this structure; the ganglion itself lies between this prolongation, which is attached to the bone, and the dura mater which covers the brain, the ganglion having a sheath of its own surrounding it and its branches. The dural sheath covering the branches of the ganglion becomes firmly attached to the bone at the margins of the foramina through which the branches of the ganglion pass. In addition to this dural sheath, there is a fine veil-like sheath, intimately connected to all parts of the ganglion, which is known as the tunica propria. The dura mater has certain points of attachment which are more firm than others. The first firm point of attachment is that around the foramen rotundum, next around the foramen lacerum anterius, and lastly around the foramina ovale et spinosum. This refers to the attachment of the dura mater to the bone; on the other hand the dura is attached in varying degrees of firmness to the surrounding structures. The first to be considered is the attachment to the ganglion itself. The most adherent point is on the upper surface; at this point the intervening sub-

*Read before the St. Louis City Hospital Alumni Society.

stance between the ganglion and the brain is the dura mater. In order to separate the dura from the ganglion, gentle dissection should be done, lest the dura be ruptured and the brain substance exposed. The attachment of the dura mater to the cavernous sinus is not firm at any point, excepting along the inner side of the first branch of the ganglion; the attachment here is really between the dural sheath of the ganglion and the cavernous sinus. Gentle dissecting with a blunt dissector will separate these last-named structures without any great amount of damage to the parts within the sinus. The attachment of the dural covering of the ganglion to the structures beneath it, is one of the most important considerations of the operation, as it is at this point that the inner portion of the ganglion is in intimate relation with the internal carotid artery. The attachment here is very firm and considerable force is required to separate the ganglion from the dura. The importance of having the ganglion free at this point is that it can be pulled away from the vessel while being evulsed from its bed. It is also important that the inner border of the ganglion should be entirely separated from the cavernous sinus, as this structure is also liable to be torn in the removal of the ganglion. It is a very peculiar condition that the branches of the ganglion are not so adherent to the underlying dura as the latter is to the ganglion itself. This is particularly so at the inner border of the ganglion, this point being most intimately connected with the internal carotid artery and the cavernous sinus, a condition that in a great measure increases the difficulty of the operation. Of the three branches of the ganglion, the first is the most adherent; in its relation with the outer wall of the cavernous sinus, from the point where it leaves the ganglion to the foramen lacerum anterius, it is very intimate, as it is firmly attached its entire length to the outer wall of the sinus. Its connection with the sinus becomes most firm as it approaches the foramen lacerum anterius, a fact which explains the difficulty which arises upon attempting to separate it for its entire length.

The dural attachments of the second and third branches are firm only at the margin of the foramina through which they pass. The dural attachment of the foramen spinosum is very firm; the dura is very thick at this point and permits of considerable force being used, so that it can be easily separated from the third branch of the ganglion without much danger of rupturing the middle meningeal artery.

The point of force, however, should be in the space lying between the foramen spinosum and foramen ovale, but sometimes the foramen spinosum is so close to the foramen ovale that the dura cannot be separated at this point.

The third consideration is that of the distribution of the blood vessels. The middle meningeal artery has always been a source of trouble in removing the gasserian ganglion. It begins usually at the foramen spinosum, which lies behind and somewhat external to the foramen ovale, passing forward for about one and one-half inches and dividing into the anterior and posterior branches, its course being upward and forward. The distribution of this artery varies considerably, as it does not always pass through the foramen spinosum. Sometimes it lies between the foramen rotundum and the foramen ovale near the foramen lacerum medium; at others it is not present at all. In the latter instance the artery passes through the foramen ovale. It is rarely found near the foramen rotundum, lying internal to this structure. In this instance the artery passes immediately over the foramen rotundum, its course being upward to the overhanging border of the lesser wing of the sphenoid, from which point it passes along to the outer extremity of the lesser wing and thence over to the parietal bone. This course of the artery offers the greatest obstacle to the complete removal of the ganglion, owing to its close proximity to the inner border of the last named structure, a point at which naturally there are very strong attachments to the surrounding structures. The dissection of the dura mater is difficult at this point, as any undue force would result in the rupture of the artery, and owing to its deep-seated location, ligation of the vessel is almost impossible. When the artery passes through the foramen ovale, it does not offer any obstacle, as it can be ligated at this point. The cavernous sinus is made up partly of nerves and veins, the veins each having a separate wall of their own, so that breaking simply into the sinus is not attended with any serious hemorrhage; should any of the smaller veins be ruptured at this point, packing for a period of ten minutes would arrest all bleeding.

The nerves lying within the cavernous sinus are the third, fourth, and sixth. The third and fourth lie high up under a reflection of the dura mater, the sixth lies close to the inner wall of the sinus and external to the internal carotid artery in close relation with the first branch of the Gasserian ganglion, as it passes through the sphenoidal fissure. The third and fourth nerves are rarely injured unless the entire outer wall of the sinus is grasped with forceps while one is endeavoring to remove the ganglion, a procedure which is unnecessary when the ganglion is dissected free from the surrounding parts before the endeavor is made to remove it. The sixth nerve is especially liable to be injured, even with the most careful dissection, as it lies immediately on the inner side of the first branch of the ganglion, on the outer wall of the sinus, as it passes through the sphenoidal fissure. The separation of the sixth nerve from the first branch can be accomplished by beginning at the base of the first branch upon the ganglion, working forward and upon this last-named structure. In this way the connection with the sixth nerve is severed by virtually shelling out the first branch for about one-quarter inch from the body of the ganglion. This permits the cutting of the first branch without any injury to the contents of the sinus. The internal carotid artery lies directly inward on a line with the third branch of the ganglion and immediately under the inner border of the last-named structure. It is intimately connected with the dura of the ganglion, so that the separation of the artery and ganglion requires careful dissection. No attempt to remove the ganglion should be made until the point of the dissector can be seen freely on its inner border. A neglect of this part of the technique will make the removal of the ganglion a hazardous undertaking. This is also referable to the separation of the ganglion from the cavernous sinus. There can be no differentiation of the tissues unless the ganglion is completely separated from the surrounding parts. The artery would be liable to be injured in applying the forceps on the ganglion, or a hole would be pinched in the artery during the evulsion, if the ganglion could not be raised free from the artery before the forceps is applied. The vessels which supply the ganglion itself are of no consequence, as the hemorrhage produced in rupturing them is easily controlled by packing.

A study of the anatomy of the sixth nerve shows that it is located on the inner wall of the cavernous sinus, external to the internal carotid artery; and no particular reference is made to its relation with the first branch of the Gasserian ganglion. The sixth nerve as it passes forward in the cavernous sinus

comes in close relation with the ophthalmic nerve as this structure passes through the sphenoidal fissure—in fact, it is intimately connected with the last-named nerve, so that any undue violence exerted on the first branch of the ganglion is almost certain to injure the sixth nerve. To illustrate how closely connected these two nerves are, traction on the ophthalmic nerve will pull both nerves outward, a fact which shows the necessity of a complete separation of these two structures before the ganglion and its branches are removed.

The technique which I have followed in removing the ganglion, is as follows:

The route selected is that of Cushing, or the so-called median route, at a point just above the temporal pterygoid ridge. An elliptical flap, consisting of the skin, muscle, and zygoma, is made, the base of the flap being the zygoma. This is turned downward, exposing the temporal fossa to the temporal pterygoid ridge. The temporal muscle is deflected downward with the periosteum, the bone being completely bared of any soft structure. After this the rough vertical ridge, which corresponds to the junction of the temporal bone and the greater wing of the sphenoid, is found. A point on this ridge, one-half inch above the temporal pterygoid ridge, is selected, and a hole is chiseled through the cranium at this point, and a piece of bone sufficiently large removed, so that a blunt dissector may be inserted in order to separate the dura mater from the skull. This is done in order to prevent any possibility of injury to the middle meningeal artery or the dura. After separating the dura the original hole is enlarged with a rongeur, the size of the hole having a horizontal and vertical diameter of about one and one-quarter inches. The lower boundary of this hole should be extended downward to the floor of the middle fossa. In order to approach the foramen rotundum, rongeuring should be forward and downward towards the orbital plate of the sphenoid bone. By following this direction, we escape any vessels belonging to the pterygoid plexus of veins. This procedure will enable us to approach within one-half inch of the foramen rotundum, and thereby permit an easy dissection of the dura mater at this point. After the aperture has been enlarged sufficiently to permit of inspection of the anatomical relations of the Gasserian ganglion, the middle meningeal artery is examined in order to locate the exact point where the artery enters the cranial cavity, and its course. After this the dura is separated by working forward on the floor of the middle fossa toward the foramen rotundum. At this point the dura mater is usually very firmly attached and offers a landmark for localizing the second branch of the ganglion. By dissecting gently on the bone around the foramen rotundum the dura is broken through at this point and the nerve exposed. After the nerve is thoroughly exposed and the dissector can be passed around it, the dissection is carried backward toward the ganglion, following the nerve and gently breaking through the dura until the body of the ganglion is reached. After this, the dissection is downward on the portion of the ganglion lying between the second and third branches, toward the third branch until the anterior border of this structure is exposed. The dura is then slightly raised from the upper surface of the ganglion. This dissection should be done wholly on the ganglion and its branches, and not outside of the limits of these structures. The next step is to separate the dura from the upper edge of the foramen lacerum anterius. The dissection should be performed on the bone just outside the edge of the foramen, to avoid injuring any of the structures at this point. The dissector should be pressed firmly against the bone until the dura is separated at this point. After this the dura should be raised in front of the foramen in order to permit a view of the first branch of the ganglion as it passes through the fissure. The dissector is then carried backward upon the first branch of the ganglion until the body of the ganglion is seen. It is then carried downward and outward over the body of the ganglion until the dissector rests on the posterior border of the third branch of the ganglion. This movement effects the greatest separation of the dura from the ganglion and the surrounding parts without any injury to the important blood vessels, and allows the brain to be retracted upward without any tension being put on the structures lying in the middle fossa. Sometimes it is necessary to separate the dura from the first branch of the ganglion by beginning on the body of the ganglion and working forward toward the sphenoidal fissure. After an inspection of the work done up to this step, the middle meningeal artery is separated from the posterior border of the third branch of the ganglion. This is done by inserting the point of the dissector just behind the posterior border of the third branch, separating the dura from this structure and also breaking through the dura that lies between the artery and the third branch. This permits of a greater separation of the dura at this point, a result which would not be easily obtained if this step was neglected. The dissector is now inserted beneath the third branch on its posterior border, the dissector lying between the nerve and its dural covering, and is carried backward until the lower border and the trunk of the ganglion are exposed. This should be done without any effort to raise the ganglion or trunk. Our next effort is to expose the remaining portion of the upper surface of the ganglion and the first branch. This is best done by beginning the dissection on the upper surface of the ganglion at the point where the dissection was discontinued in order to expose the third branch. The dissection is carried upward toward the first branch, and carried on this structure to a point one-quarter inch from the ganglion. The dura surrounding the ganglion is now reflected upward toward the cavernous sinus. This procedure enables us to see the inner border of the ganglion. When this is exposed, the point of the dissector is inserted between the inner border of the ganglion and the dura, which is dissected from the ganglion. This enables us to push the point of the dissector forward and along the first branch, so that this structure is shelled out of its dural sheath without any injury to the contents of the cavernous sinus. After this, the point of the dissector is placed at the under edge of the first branch, between this branch and the dural sheath, and carried backward toward the body of the ganglion and from thence down on the second branch. After the first branch is thoroughly exposed, the edge of the dissector is again placed between the inner border of the ganglion and the reflected dura and carried backward until the inner border of the trunk is exposed. The ganglion and its branches are now completely separated from the tunica propria and the dura on its upper surface.

The next step is to remove the ganglion from its bed. This really means a detachment of the dura from the under surface of the ganglion; and this must be done in order to separate the ganglion from the internal carotid artery. The procedure is as follows: The point of a flexible blunt dissector, which is curved to meet the contours of the cavum Meckelii, is inserted between the second and third branches of the ganglion, the point slipping in between the under surface of the ganglion and the dura; the dissector is then pushed backward and inward, a sweeping move-

ment being made, so that all attachment between the ganglion and dura is broken. This procedure is followed by considerable hemorrhage, which requires packing for about ten minutes for its suppression (when removing the ganglion in the living subject). After the hemorrhage is stopped the dissector is again inserted between the second and third roots of the ganglion, and the lower and outer borders of the ganglion are separated from any remaining dural attachment. The inner and under surfaces of the ganglion are freed from any remaining dural attachment by carrying the dissector along the inner and under surfaces of the ganglion. When the under surface of the ganglion is completely free from all dural attachments, the point of the blunt dissector can be seen at the inner border of the ganglion. This point must be carefully observed, for it offers an assurance that the cavernous sinus is free from the inner border of the ganglion and also that the internal carotid artery is not attached in any way to the under surface of the ganglion. In performing this dissection, care should be observed that the point of the dissector is inserted between the ganglion and its dural covering, so that the ganglion and dura are not raised together. If this should occur there would be firm attachment between the ganglion and the internal carotid artery, so that the removal of the ganglion would be attended with the danger of tearing a hole in the artery. The next step is to insert the point of the blunt dissector under the posterior border of the third branch of the ganglion and carry it back and well under the trunk of the ganglion. This movement separates the under surface of the root of the ganglion from any dural attachment.

The ganglion is now freely exposed and the trunk is in a condition for the application of the evulsing forceps. This is done with forceps properly curved and having a long biting blade. The under blade of the forceps is first slid under the trunk of the ganglion, the tip of the blade showing beyond the inner border, but not enclosing any of the other structures. A careful observation should be made that none of the dura mater surrounding the cavernous sinus at this point is within the grasp of the forceps. After the assurance that only the trunk of the ganglion is within the curve of the under blade of the forceps, the blades are closed and firmly clamped. Before the blades are clamped, their tips should be diverted in a direction backward, so that they are away from the internal carotid artery. The next step is to pass a hook around the second branch of the ganglion, pull it forward toward the aperture in the skull, and divide it near the foramen rotundum. After this, the third branch is divided in the same manner, a hook being passed around it and traction being made so that the nerve is drawn toward the hole in the skull; it is then divided near the foramen ovale. To make sure that there are no attachments between the under surface of the ganglion and the internal carotid artery and the cavernous sinus, a flexible curved dissector is once more passed beneath the ganglion and this structure is raised from its bed. The finger is inserted underneath the ganglion to palpate the internal carotid artery. This will give more definite information as to the surrounding structures. The evulsing forceps is now grasped and the trunk is torn from its attachment to the pons, care being taken that traction is not made from the direction of the cavernous sinus, but wholly on the trunk in a direction forward and toward the ganglion. This procedure will prevent the cavernous sinus being pulled forward by any possible remaining attachments that may exist between the ganglion and the sinus. If there should be any remaining attachments between the cavernous sinus and the ganglion, the curved flexible dissector is again passed between the sinus and the inner border of the ganglion and the outer wall of the sinus is pushed inward, thereby separating this structure completely from the body of the ganglion and at the same time freeing the first branch of the ganglion from the sinus. Traction should now be put upon the ganglion so that it will be pulled directly away from the sinus in an outward direction toward the opening in the skull. This will pull the first branch of the ganglion away from the sinus, and permit it to be cut about one-eighth inch from the ganglion. The curved scissors, which are used to sever this last-named structure, are inserted in such a direction that the blades pass around the nerve from behind, so that the points are directed forward and away from the cavernous sinus. This precaution is necessary as it is possible to cut into the sinus if the points are directed backward. The ganglion is now completely free from all attachments and is removed in its entirety.

I have not mentioned anything regarding hemorrhage during the foregoing steps of the operation, as I think it is better to describe that under a heading of its own and emphazise the particular points in the operation in which we are liable to have severe hemorrhage. The separation of the dura is attended with considerable loss of blood, but this is of no consequence, as packing for one-half or one minute is sufficient to arrest it. As we approach the ganglion the hemorrhage becomes more profuse, and considerable bleeding occurs when the dura is raised from the upper surface of the ganglion; this is easily controlled by packing and does not delay the operation over five minutes. Separation of the dura from the first branch, downwards and toward the ganglion and from thence to the third branch, is attended with some hemorrhage, but this usually stops spontaneously. The dissection of the tunica propria from the upper surface of the ganglion is never attended with hemorrhage of any consequence. The ganglion at this stage of the operation is usually visible, so that every move of the dissector is plainly seen. During the separation of the ganglion from the cavernous sinus, the sinus in most cases is open. This is of no consequence unless one of the vessels in the sinus is ruptured, an occurrence which is impossible if the dissection is done with a blunt dissector. Separating the under surface of the ganglion from the dura mater is attended with profuse hemorrhage. The work at this point should be done rapidly and vigorously. There is no danger of injury to any of the important vessels, as the dissection is done with a blunt dissector. The hemorrhage at this point is usually the most severe, but here again packing for ten minutes will completely arrest it, so that the dissector can be inserted underneath the ganglion and a more complete separation secured. There should be no further severe hemorrhage unless the middle meningeal artery or the internal carotid artery is injured. This is scarcely possible if careful dissection of the ganglion is made.

After the ganglion is removed, the middle fossa should be thoroughly packed with sterile gauze, which is allowed to remain until the skin flap is approximated by several anchor sutures. The packing is then removed. Should the hemorrhage continue after the packing is removed, the latter is inserted again and allowed to remain for twenty-four hours. Ordinarily this last procedure is not necessary, as the brain usually fills out the middle fossa, and the weight of this structure is great enough to produce pressure sufficient to stop all hemorrhage from the small vessels.

In operating upon the cadaver, the relative hemorrhage that is met with in certain operations cannot

be ascertained. To obviate this I shall suggest a method that is original with me, so far as I know. And I ask earnest criticism on various points that I shall present concerning my efforts to produce artificial circulation in the cadaver. My plan is as follows: The nozzle of a Davidson syringe is inserted through a slit in the common carotid artery and a suture is passed around the artery so as to fix the nozzle of the syringe securely within it. A solution of carmine is injected into the artery, an assistant squeezing the bulb of the syringe rhythmically to imitate the impulse of the heart. The carmine solution is forced in the vessels, distending them so that those around the Gasserian ganglion are full and pulsating as in life, and should any of the vessels be injured during the dissection of the ganglion from its attachments, the solution will immediately flood the field of the operation. It was through this procedure that I ascertained that breaking through the under surface of the ganglion was attended with more hemorrhage than dissection at any other point. This procedure also gives a good illustration of the close proximity of the internal carotid artery to the Gasserian ganglion. The middle meningeal artery is more plainly seen, and in every way we gain a definite idea as to the points at which the greatest hemorrhage is to occur in the living. I would recommend this plan in all operations on the cadaver, as it will give one a more definite idea as to the location of the arteries at any site in the human body. When the arteries are distended no information is given as to the relation of the veins. If the location of the veins should be desired the syringe is to be attached to a large venous trunk; this will distend the veins in any part of the body that one may desire to operate upon.

In conclusion, I must emphasize several points in the operation of removing the Gasserian ganglion:

1. A careful dissection of the ganglion from the dura and other contiguous structures must be made; the dissection being made upon the ganglion and its branches as much as possible. If we keep upon the ganglion and its branches there will be very little hemorrhage. On the other hand, should an effort be made to dissect the ganglion by working upon the surrounding structures, a profuse hemorrhage will be produced.

2. The ganglion must be dissected from its dural covering; the cavernous sinus, internal carotid artery, and middle meningeal artery should be completely separated from the ganglion before any effort is made to evulse it. In my experience, I have found that it is best first to divide the second and third branches, and then break through the trunk of the ganglion and pull it away from the cavernous sinus before any attempt is made to cut the first branch of the ganglion. This procedure will enable the operator to avoid the sixth nerve and the contents of the cavernous sinus.

3. The last consideration is that of hemorrhage. In the three cases in which I have seen the Gasserian ganglion removed from the living subject, I assisted in two operations, and in the third I removed the ganglion myself. In each of these cases the hemorrhage was controlled at all times by packing. The first case, operated upon by Dr. Bartlett of St. Louis, might be considered a very unfavorable one, as the patient had passed 60 years of age, and had marked arteriosclerosis; consequently we encountered quite a severe hemorrhage. But even in this case packing controlled the hemorrhage, so that the ganglion could be seen during the greater part of the operation. In the second case, the hemorrhage was controlled at all times by packing. In my own case, the hemorrhage was practically nil. At no time was it necessary to pack for over five minutes; the ganglion was visible at all times, and an inspection of the middle fossa could be made, so that a differentiation of the tissues was possible. Physical conditions favoring hemorrhage are old age and arteriosclerosis. In the middle aged and the young very little hemorrhage is encountered.

PRIMARY CARCINOMA OF THE TIP OF THE APPENDIX; PRIMARY EPITHELIOMA OF THE SPHINCTER MUSCLE OF THE BLADDER.*

By J. RIDDLE GOFFE, M.D.,

PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC; VISITING GYNECOLOGIST TO THE NEW YORK CITY HOSPITAL, ETC.

The two cases I present are of interest, not only on account of the unusual location of the malignant growths, but also as suggesting, especially the second case, an obscure cause of refractory and annoying bladder symptoms. The cancer of the appendix is the more surprising from the fact that it occurred in a young girl only fifteen years of age. The patient was a Jewess, unusually well developed for her years, of ruddy complexion and well nourished. For more than a year she had complained of a steadily increasing pain in the appendiceal region, whenever she indulged in any ordinary physical effort, such as walking, running, jumping the rope, or climbing stairs. Her family physician had made a diagnosis of subacute or chronic appendicitis and advised operation. With this I coincided, although no tumor could be palpated. A mental reservation accompanied this to the effect that the symptoms might be produced by some pathological condition of the right uterine appendages. I operated December 4th, making a free incision over the appendix to permit of careful inspection of the ovary and tube. The successive layers of muscles were split in the direction of their fibres and the peritoneal cavity was entered. The appendix was unusually long, was thickened and tortuous, and in the extreme tip could be seen through the peritoneum, which was tightly stretched over it, a perfectly round white body about the size of a large marrow-fat pea. The appendix was amputated, the stump being inverted into the lumen of the gut. The uterine appendages were then palpated and found normal. The wound was closed without drainage.

The little tumor looked and felt like a calculus, but to my surprise, upon cutting down upon it, it appeared to be organic tissue resembling a fibroid tumor. On careful inspection, it was clearly evident that it was not in the lumen of the appendix, but had developed in the tissue, between the mucous membrane and the peritoneum. The specimen was refered to Dr. F. M. Jeffries at the laboratory of the Polyclinic, who reported as follows: "Acute appendicitis throughout the entire organ, no evidence of chronic inflammation discoverable. A small spherical nodule five millimeters in diameter was found at the extreme tip, which upon microscopical examination proves to be carcinoma of quite typical character. A few gland structures lined with goblet cells are scattered throughout the stroma, which are probably follicles of Lieberkühn. At one point in the muscular coats adjacent to the nodule, a marked infiltration of growth is apparent, though this is not found beyond a certain limited area. I have been unable to determine the point of origin in this case. The growth appears to intrude wholly upon

*Presented at a meeting of the New York County Medical Association, held at the Academy of Medicine, March 18th, 1901.

the lumen of the appendix, the muscular coat remaining unaffected, other than by the invasion described."

(Signed) F. M. JEFFRIES.

Dr. Jeffries reported to me verbally that two prominent pathologists of the city had confirmed his diagnosis, one of them remarking that this was the second instance that had come to his notice of primary cancer of the appendix, the other never having known such a case before. This report of the pathologist suggested the importance of securing the family history, and I found that the paternal grandmother, who is now living, had suffered from cancer of the uterus, for which she had submitted to vaginal hysterectomy about four years ago, and the grandmother's sister had been afflicted with cancer of the breast. The family is a large one, but no one of the patient's generation or the one preceding it had had malignant trouble. The prognosis of the present case becomes therefore extremely interesting. The patient convalesced promptly and has been entirely relieved of her former symptoms.

The second case was that of an unmarried woman, 28 years of age, who had suffered with extremely annoying symptoms from frequent and painful micturition for the past six years. The symptoms had been steadily progressive both in frequency and severity until within the last few months; her nights had been robbed of sleep and the suffering, at times, had been intense, the pain being exaggerated during and following her menstrual periods. Previous to my seeing her, she had been in the hands of several gynecologists and had undergone treatment for displacement of the uterus and anteflexion, but without relief. I speak of this simply to emphasize the point that the condition was sufficiently unusual to elude discovery, although when once the sense of touch had given the intimation of the presence of a growth its existence became positively apparent as the examination proceeded. The urine was free from any pathological conditions except an extreme excess of uric acid. Cystoscopy revealed no abnormal conditions of the mucous membrane, but the extreme dilatation of the urethra, attendant upon the cystoscopy, gave considerable relief for several days. A careful palpation of all the parts at a subsequent date, during the pressure of the tissues against the posterior face of the symphysis, detected this little tumor in the sphincter muscle of the bladder to the left of the internal urethral orifice. I supposed it to be a diseased lymphatic gland, or perhaps the first stages of a vaginal cyst, and advised its removal. Upon cutting down upon it, I found it so intimately incorporated with the muscular fibres that it could not be shelled out. This led to the suspicion that it was a growth of a most serious character and demanded wide dissection in the surrounding tissues. Accordingly, I made an incision into the bladder through which I passed my finger, and with this as a resisting body I dissected out the growth. To secure drainage from the invaded tissue the mucous membrane of the bladder was simply closed with a running catgut suture, the wound being left open and the vagina being packed with iodoform gauze. The wound was later closed with silver wire sutures, the catgut having eventually given way. The patient made a prompt recovery and has been entirely relieved of all her symptoms. The operation was done January 14th, 1901.

The pathologist's report is as follows: "Size of tissues received, 17x25 mil. Microscopical examination demonstrates this tissue to be devoid of capsule and to consist largely of what appears to be thickened bladder-wall, the increase of tissue being muscular rather than fibrous. The surface on one side is infiltrated with epitheliomatous structures. No bladder mucosa is found; but two or three saccular, gland-like structures lined by columnar epithelium and distended with fluid are found extending into the muscular tissue. The growth is an epithelioma. I hardly believe it could be possessed of any great degree of malignancy."

(Signed) F. M. JEFFRIES.

These two cases are unique in demonstrating the presence of primary carcinoma in most unusual locations. It is significant, too, that they were discovered in two unmarried women, and both at so early an age. (The slides showing, not only sections of the growth, but the condition of the surrounding tissues were shown under the microscope).

Intestinal Occlusion as a Result of Movable Spleen.—Antonio Mori reports a case. Replacement of the displaced organ by means of manipulations, with the patient in the genupectoral position and then lying on the left side, overcame the spasmodic contractions, pain, and vomiting and the functions of the intestines again became normal. The condition is rare. The author gives directions for the diagnosis of movable spleen. As to operative measures, he thinks that splenopexy can be applied in simple cases and perhaps in cases of hypertrophied movable spleen. In more complicated cases, it is a question whether fixation or extirpation is to be preferred.—*La Riforma Medica.*

Hysterical Pains in the Mastoid Process.—Liaras and Bouyer relate a series of cases of pain in the mastoid region in which a close examination has shown an absence of inflammatory conditions but occasionally the presence of a condensing osteitis. Given the existence of a mastoid pain (indefinite and not well-defined) in patients who present evidences of hysteria and in whom the local conditions point to the existence of osteitis, a positive diagnosis of mastoid involvement is impossible. But when we can rule out the existence of an osteitis the possibility of a concealed and mono-symptomatic hysteria must always be borne in mind. The treatment of such cases should be along the lines applicable to hysteria in general.—*Revue Hebdomadaire de Laryngologie.*

Five Cases of Traumatic Tetanus.—Felice D'Alessandro reports these cases in which hypodermic injections of carbolic acid, successful in Baccelli's cases, and of corrosive sublimate as advised by Baculo, were not successful. The reason for the failure he considers to have been: 1. Extreme gravity of the traumatism; 2. Gravity of the nervous shock; 3. Insufficient amount of carbolic acid. The amount of phenic acid injected should be in proportion to the weight of the individual and not less than 1 centigram ($\frac{1}{6}$ grain) to each kilogram (2$\frac{1}{2}$ lbs.) of weight. Nor should this dose be gradually reached, but it should be given at once, and diminished if any signs of intolerance appear.—*Giornale Internazionale delle Scienze Mediche.*

Curable Heart Disease, or Adolescent Heart Strain.—Albert Martin discusses a condition characterized by cardiac murmurs, but not indicating organic disease. He refers it to a want of muscular power of the cardiac muscles only, especially the musculi papillares, to whose weakened condition he ascribes the regurgitant murmurs heard at the apex. The bruit present at the base he regards as secondary to anæmia of the general system. That the cases reported were not merely anæmia is shown by the fact that iron and diet did not bring

about a cure. Treatment should consist of rest in bed, seclusion, the administration of digitalis pushed until one has the physiological effects, and strychnine, preferably in the form of the tincture of nux vomica on account of its stimulating and appetizing properties.—*The New Zealand Medical Journal.*

The Appendicular Form of Pneumonia.—P. Mirande cites a number of cases of this form of pneumonia, in which the symptoms for the first three or four days are entirely those of appendicitis. If operation is performed, a perfectly normal appendix is found, and two or three days later the key to the enigma is furnished by characteristic tubal resonance and crepitant râles. Appendicular symptoms usually disappear about the fourth day. In some cases intense and persistent elevation of temperature, flushed cheeks, and the early appearance of cough will put one on the right track for the diagnosis of pneumonia. On the other hand, the symptoms which militate in favor of appendicitis are prominence of the abdominal veins, œdema of the skin, and tenderness on pressure applied to Douglas' pouch in women and to the recto-vesical *cul de sac* in men. The difference between the rectal and axillary temperatures in cases of pyrexia amounts to between 0.02° and 0.05°, but in appendicitis may reach 1.1° to 1.4°.—*The Medical Press and Circular.*

Testing and Training Distant Vision with Special Reference to Military Requirements.—R. Brudenell Carter holds that much may be done in the way of training to cultivate rapidity and acutness of vision. The Boers are reputed to have superior vision to that of the English soldiers, but the reason probably lies in their habit of looking over great distances, using small images for their guidance. What to a Boer would be a man or an ox or a horse, would to an unaccustomed person be a something of undetermined nature. Ninety-nine English soldiers out of a hundred, after a fortnight's exercise on the veldt would see anything that the Boers themselves could see, and would interpret images as quickly. Nothing could be more appropriate to the functions of a volunteer regiment, or of an athletic club, than to cultivate excellence of vision among its members. Let children, or men make it an object of ambition to see the smallest distant object, to observe the faintest difference of color, and to notice lateral objects as well as those in front of them, and vision will be greatly improved.—*The Medical Press and Circular.*

Etiology of Pertussis.—Drs. Jochmann and Krause conclude that (1) In the majority of cases the smallest influenza-like bacilli are found. (2) These morphologically similar bacilli do not belong to one species; there are three different kinds which biologically are differentiated by their relations to Gram's stain. (3) This accounts for the varying opinions of different observers as to the biological characteristics of the bacillus observed in spread specimens. (4) The bacillus of Czaplewski and Hensel is not considered the etiological factor of pertussis, because it was seen in but four cases. (5) On the other hand, in eighteen cases and three post-mortems there was found an influenza-like bacillus which, in contradistinction to all similar bacilli described, are characterized by their exclusive growth on media containing hæmoglobin and which they call bacillus pertussis Eppendorf.—*Zeitschrift fur Hygiene und Infections-Krankheiten.*

Experimental Lumbar Puncture for the Determination of Tubercle Bacilli.—Hellendall says that the detection of tubercle bacilli in the spinal fluid is not always positive; more uncertain still are animal experiments and the injection of the suspected fluid into the peritoneal cavity of the guinea pig. The author attempted to produce tuberculous meningitis by injecting into the meninges of guinea pigs tuberculous spinal fluid. The experiments undertaken with eight guinea pigs showed that five died from general miliary tuberculosis (one to three weeks). Two died within twenty-four hours and hyperæmia of the spinal cord and brain was found post mortem. Therefore, tuberculous meningitis was not produced. From these experiments, however, it is seen that for the determination of tubercle bacilli in the spinal fluid animal experiments are more exact than the examination of microscopical preparations. Intrameningeal injection is more rapid in its effects than intraperitoneal; furthermore, less fluid (2 cc.) is required for intrameningeal than for intraperitoneal (4 cc.) injection. Again the lumbar fluid is a better culture medium for the tubercle bacilli.—*Deutsche Medicinische Wochenschrift.*

Occult Gastric Hemorrhages.—J. Boas says that hemorrhage from the gastric mucous membrane occurs either as a severe gastrorrhagia or as a minute capillary bleeding from ulcers or ulcerating tumors; in both instances the blood retains its normal color or assumes a coffee-ground appearance. In very small hemorrhages, with an acid medium, no apparent change takes place in the color of the gastric contents. Numerous specimens of the gastric contents, which upon closest inspection gave no evidence of blood, showed a greater or less amount of blood, when examined by the guaiacum test with Weber's modification; for this purpose freshly-prepared tincture of guaiacum is necessary. This gives the most distinct reaction, especially when, after adding the tincture of guaiacum and turpentine oil, the ethereal solution is well shaken with chloroform and water and allowed to stand for some time. For purposes of examination the stomach contents procured by means of a tube is preferable to the vomited matter; the latter, even under normal circumstances, may contain small quantities of blood which does not come from the stomach. Furthermore, care must be exercised against artificial hemorrhage due to severe pressure which causes erosion of the mucous membrane. In eighty-three cases of various gastric ailments and a few intestinal troubles, the stomach contents were examined. The stomach diseases were divided into three groups: those in which blood was constantly absent, those in which hemorrhage occasionally appeared, and finally those in which repeated examinations showed the constant presence of blood. In the first group were neuroses, cases of an acid gastritis, one case of subacid gastritis, cases of hyperacidity, of hypersecretion, and of benign ectasia. Among the cases of alternating hermorrhage are those of gastric ulcer and consecutive pyloric stenosis. In the third group may be mentioned hypertrophic stenosis of the pylorus and twenty cases of carcinoma ventriculi. In these cases, blood was always found in the gastric contents, irrespective of the chemical or motor functions of the stomach. Occult gastric hemorrhages have no positive diagnostic significance, but they are important in a differential sense.—*Deutsche Medicinische Wochenschrift.*

Children of Neurasthenic Parents.—Ad. Czerny concludes: 1. These children should associate as much as possible with others. By this means, as well as through occupation and play, observation of themselves and of diseased condition of adults will be overcome. 2. All disagreeable prophylactic curative measures as well as medical treatment is to be avoided; also all procedures which tend to show the child that he is ill or unusual in temperament. 3. Neuropathic parents must not speak to them of their own ailments or those of others. 4. Only in urgent cases are the children to be kept from school. 5. Parents are to be informed by the physician of the dangers and difficulties in bringing up such children.—*Deutsche Zeitung.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR,

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue:

New York, July 6, 1901.

PATHOLOGY AND TREATMENT OF SUNSTROKE.

THERE is no argument necessary to prove that heat in itself is the prime causative factor of sunstroke. Most commonly, it is true, the phenomena variously grouped under the designations of insolation, *coup de soleil* and *sonnenstich* are due to the intensity of direct solar rays; they are also induced by artificial heat in shady quarters, and even during the night, when high temperature and extra humidity prevent the proper cooling of the body by natural evaporation.

Although different grades of heat-exhaustion are given with their corresponding varieties of pathological lesions, it is fair to assume that they depend essentially upon different degrees of action of the primary factor.

The study of autopsical lesions in given cases is not always satisfactory in reconciling relations of cause and effect. When death is sudden, no distinctive tissue changes are manifest. Under such circumstances, the condition appears to be either that of syncope from simple failure of heart action, or from direct shock to the cerebral and respiratory centers. The latter, termed the asphyxial form, is the most common, and most rapidly fatal. In the hyperpyrexial variety, in which the temperature may range from 108° F. to 110° F., the cerebral lesions are usually quite pronounced. There are often evidences of meningitis, serous effusions in the ventricles, and, occasionally, hemorrhages into the brain substance. In spite of these pathological appearances, mostly focused, as they seem to be, in the cerebral centers, the cause of death is asphyxia and not apoplexy. As evidences of this fact, the lungs are deeply congested, the entire venous system is engorged, the heart is firmly contracted, and the blood is dark, impaired in coagulability, and has increased fluidity. In a general way, we may, perhaps, explain the existence of the various lesions by the assumption that in all the cases the brain and nervous centers, especially the respiratory, are overwhelmed by the sudden elevation of temperature, and respiration and circulation eventually fail—the latter being probably due to the inhibitory influence of the vagus. It is simply over-stimulation by heat, followed by eventual exhaustion.

In the hyperpyrexial form in which the symptoms come on more gradually and continue proportionately longer than in the other varieties there appears to be more time and more opportunities for permanent lesions in brain structure. Thus in those who recover from the immediate attack, there may be marked and permanent impairment of intellect, frequent headaches, due to subacute meningitis, also loss of memory, eyesight, and hearing, muscular paralysis, and other evidences of permanent absence of nerve force. There can be no question that these changes thus induced are distinctly and diffusively organic in character, although, as yet, such are not absolutely explained by any manifest degeneration in nerve cell structure, or in any uniform retrograde metamorphosis of nerve fibre. The gross lesions are, however, plainly enough seen to enable us to hope that the discovery of the finer ones may be only questions of time, opportunity, and study.

We only glance cursorily at the general pathology of *coup de soleil*, in order to appreciate such practical matters for treatment, as may be thereby suggested. Everything in the way of a promise of absolute recovery depends upon the prompt treatment of the initiatory symptoms. It is only in this way that permanent lesions can be anticipated or prevented. Once the organic changes are fixed, the victim becomes a hopeless invalid, with impairment of his most valuable faculties. The main therapeutical indications are in the direction of modifying immediate shock, and of reducing more or less rapidly excessive temperature. In this connection, it is well to recollect the numbers of important centers involved, and the intimate associations of some of these with the respiratory and cardiac functions. While it is somewhat doubtful that local cold douches to head, neck, and spine can do much more than lower surface temperature they certainly, even in this indirect way, often accomplish wonderful results. It would seem almost like blowing hot and cold with the same breath to advise heart stimulation in connection with the foregoing measures, but in reality by so doing, we effectually counter-balance the effects of the ultimate exhaustion which always follows the primary over-stimulation. In fact, we may work them side by side as indications may demand. It often requires the most careful watching to know when to lean more on one side than the other, and even under most favorable circumstances the game may be a losing one, as it must be recollected that the usual mortality is generally placed at from forty-five to fifty per cent.

The main object to be kept in view is the rhythmic restoration of co-ordinating vital forces. The latter must be coaxed into line rather than forced. Hence the powerful antipyretics are apt to be dangerous and defeat their object, as well as the more potent and pronounced cardiac stimulants.

In spite of prompt therapeutic measures, there are so many relapses in the shape of subsequent intolerance of solar heat, that the conviction is almost irresistible that in the majority of the severe cases some intricate and undemonstrable organic nerve degeneration is a foregone conclusion. During the present hot and sultry season, there are and will be abundant opportunities for according theory with practice, and for remembering that sunstroke, in any of its forms, is a very serious calamity to the victim, requiring the greatest skill on the part of his medical attendant in meeting the many complex conditions likely to present themselves.

THE TYPES OF DYSENTERY IN THE PHILIPPINES.

The study of tropical diseases by the medical department of our army in the Philippines is being attended with excellent practical results under authority from the Surgeon-General, with a view of presenting to the medical officers of the Division of the Philippines the results of the investigations that have been made by Lieut. R. P. Strong, Assistant Surgeon in the pathological investigation of these ailments. The latter gentleman has been instructed to prepare a series of circulars, each being an epitome of the subject studied. The second of these circulars, treating of army dysentery as observed in and around Manila, has just been published.

We are not surprised to learn that the disease in question is alarmingly prevalent among our troops, serving in that far off region. During the past twelve months there have been over four hundred deaths from dysentery. This mortality is nearly four times as great as that from any other single malady. The statistics show that of 1,830 cases admitted in the First Reserve Hospital during sixteen months only one-third have been returned to military duty. Of the two hundred and twenty-one autopsies made in Manila, one hundred and eleven have been upon dysenteric cases.

All these facts show the imperative necessity of studying the pest in all its varied bearings, bacteriologically, pathologically, clinically, and therapeutically From these points of view, Surgeon Strong has certainly made a very suggestive study of his subject. As a result of his investigations, he is led to believe that in and around Manila there exist at least two distinct varieties of dysentery—one infectious in character depending upon the bacillus dysenteriæ (discovered by K. Shiga in 1898), and the other an amœbic dysentery having, of course, an entirely different etiological factor. The bacillary form is an acute infectious disease characterized anatomically by an extensive superficial necrosis of the mucosa and usually by hyperplasia and hemorrhagic infiltration of the lymph follicles of the large intestine, with induration and thickening of its walls, by hemorrhagic swelling of the adjacent mesocolic glands, and often by parenchymatous changes in other organs. The bacillus dysenteriæ is present in the acute stages of the disease, both in the discharges and in the superficial necrotic layer of the intestinal mucosa.

Clinically the disease has an acute onset, with frequent mucous and bloody stools and marked tenesmus; often the patient goes to bed feeling perfectly well and during the night may have from twenty to forty stools. The duration of active symptoms is from four to fifteen days, at the end of which time convalescence begins or death occurs

This form of dysentery seems widely spread over the Island of Luzon and is most frequent toward the end of the rainy season.

So far as can be learned, infection occurs through the drinking of water and milk, although the supply of the latter is quite limited. Uncooked food (salads cresses, etc.) is an important etiological factor. Catarrhal affections, indigestion, constipation, and starvation are predisposing causes.

The morbid anatomy of infectious dysentery is quite characteristic and is markedly distinguishable from the amœbic variety. On opening the abdominal cavity, the intestines externally appear almost healthy. In a large majority of cases, the mesenteric vessels of the large intestine are injected. The lymph glands along the upper end of the rectum and sigmoid flexure are swollen, red, and hemorrhagic. No circumscribed and deeply seated areas of necroses are visible. The other lymphatic glands along the larger bowel are only slightly affected, although the group running towards the head of the pancreas is markedly involved. The mucosa of the large intestine presents a reddened, swollen, and puffy appearance throughout its whole extent with a superficial necrotic layer composed of mucus, red blood corpuscles, leucocytes, epithelial scales, swollen granular scales, and bacteria. No amœbæ are found. Here and there purpuric spots may appear in the small intestine, the lower portion of the mucosa is reddened, but only in one-third of the cases is it extensively involved. The other organs show no constant changes. The spleen and liver may be moderately swollen. In no case was liver abscess present, although in the subacute stage fatty degeneration existed. The very interesting point in this connection, is the statement of Dr. Strong to the effect that "in no text book at hand can we find a description of this form of acute infectious dysentery as we see it here."

The bacillus dysenteriæ may be obtained from the superficial necrotic layer and exceptionally from the hemorrhagic mesocolic glands. Bearing in mind that the acute infectious variety is bacillary in character and prevails in epidemic form, while the amœbic dysentery, depending solely on infection with a protozoon, is essentially endemic throughout the year, so far as is known to the contrary the same predisposing and exciting factors exist in both.

In the amœbic form there are marked periods of exacerbation and intermission and the onset is gradual. The pathological conditions also match the clinical manifestations. In general there was extensive thickening of the large bowel with numerous soft, deeply undermined, ragged-edged ulcers, often raised above the surrounding mucosa by underlying infiltration. In many cases, both healing and fresh lesions were observed, in others there was perforation with peritonitis. Fourteen of the ninety-seven cases examined autopsically showed characteristic liver abscess containing amœba. Not only may the amœbic and bacillary dysenteries be differentiated post-mortem but they may be easily separated with two groups during life, one infection being recognized by its specific blood serum agglutination for the bacillus and the other by the presence of the parasite amœba dysenteriæ in the stools. These carefully-made observations are of great practical interest not only to the student of tropical medicine but to all practitioners who are called upon to treat dysentery as it prevails in different sections of the United States. The painstaking methods employed at the army laboratory at Manila are a credit not only to the medical department, but to the science of bacteriology in general, and prove the wisdom and forethought of Surgeon-General Sternberg, who is himself a high authority in such lines of research and has ever been the foremost advocate of progressive methods of pathological study.

THE TREATMENT OF SOME APPARENTLY INCURABLE EYE AFFECTIONS.

The mainstay of the successful physician must ever be hope. It is true that recovery will take place spontaneously from many morbid conditions, but in the vast majority of instances this will be favored by, if it do not actually require, the intervention and guidance of the intelligent therapeutist. The remedies employed need not necessarily be drugs; in fact, the greatest good is often brought about by means of physical or physiological agencies. We may not always be able to explain the mode of action by which the good is affected, but meanwhile well substantiated empirical observation and practice are not to be despised. Of the force of the foregoing remarks illustrations will be found in a clinical lecture delivered a short time ago by Dr. Charles Bell Taylor (*Lancet*, April 27, 1901), in which are related a number of remarkable instances in which sight was restored to persons who were believed to be incurably blind. This was accomplished in part by means of electricity, mercury in large doses, alone or in combination with other drugs, derivatives, together with such operative measures as seemed indicated by the needs of the individual case. Thus, electrolysis will be found most useful in the treatment of angiomata, inoperable tumors, adenoids, granular lids, and other abnormal growths. As a cauterant, a cataphoric agent, an illuminant of internal cavities, a destroyer of bacilli, a generator of heat and ozone, electricity is unrivalled, and the electro-magnet both as a sideroscope and an extractive agent is indispensable in the treatment of accidents of frequent occurrence. The galvanic and faradic currents are most valuable in the presence of corneal ulcers and opacities, of neuroparalytic keratitis, of paralysis of ocular, facial, and other muscles. Dr. Taylor claims further that the electric current has a potent influence upon all living protoplasm, a restorative power for which there is no substitute, not only in cases of neuritis and degeneration the result of injury, with the accompaniment of palsied muscles, but also in the presence of neuritis and degenerative changes such as accompany and follow upon attacks of influenza, diphtheria, diabetes, typhus, typhoid, rheumatism, and other febrile disorders. As a stimulant, tonic, and catalytic agent under such circumstances he believes it to be of the greatest value, and a last resort in the treatment of atrophy of the optic disc, neurasthenia, asthenopia, failing brain power, and general nervous declension such as is observed at the menopause in women, or as a result of advancing years or exhausting disease, or the abuse of alcohol or tobacco, or lead poisoning.

Mercury may be administered in the form of blue pill, ointment, vapor, or subconjunctival injections. For the last purpose the cyanide is to be preferred, the injection being made painless by the addition of a small amount of eucaine. It is frequently necessary to combine morphine with the pill, and pilocarpine is an important adjuvant. The latter may be given internally in doses of gr. $\frac{1}{2}$ or hypodermically in doses of from gr. $\frac{1}{10}$ to gr. $\frac{1}{4}$. Elaterin also is a useful aid in doses of from gr. $\frac{1}{40}$ to gr. $\frac{1}{10}$, especially in the presence of detachment of the retina.

Concerning blood-letting the advice is given to bleed early and to let the blood flow until the pain, if there is any, has quite gone. When the eye alone is affected, natural or artificial leeches may be applied to the temple with great advantage. Among other useful derivatives are sinapisms, blisters, setons, issues, icebags, hot-water bags, Turkish baths, lamp-baths with hot pediluvia, intestinal derivatives, hot and cold aspersion, and the actual or electric cautery for purposes of stimulation, counter-irritation, or destruction of tissue.

THE DIAGNOSIS OF RABIES.

Dr. D. E. Salmon, of the Bureau of Animal Industry, writes on this subject in the "Agricultural Department Year-Book," just issued, and after referring to its continuous increase in the United States, speaks of the difficulty in recognizing the nature of the malady. On this point he says that there are two forms of rabies—the furious and the dumb. In the former, the animal is irritable and aggressive, and bites nearly every object that comes in its way; in the latter, the muscles of the jaw are paralyzed almost from the first appearance of symptoms, and, being unable to bite, the animal remains more quiet and tranquil. In both forms the disease is the same and the saliva is equally deadly. The dogs with dumb rabies are less dangerous, solely because, their jaw muscles being paralyzed, they are unable to bite. The difference in the two forms of the disease is due to the greater rapidity of the development of symptoms in dumb rabies. Every case of furious rabies eventually turns to dumb rabies, for paralysis of the jaw is one of the final symptoms. What is called the "drop-jaw form" is when the symptom occurs on the first day of the disease instead of after an interval of two, three, or more days, as in the case of furious rabies. The symptoms of furious rabies appear very gradually. The animal appears restless and is very apt to become more affectionate than usual, fawning and licking the hands or face of its master as though seeking sympathy and aid. This is a particularly dangerous demonstration, for if there is the slightest abrasion of the skin there is almost a certainty of inoculation. There are many instances in which hydrophobia has been imparted to human beings in this way. Another very dangerous symptom is when the dog apparently has a bone in its throat and is unable to swallow. This simply means that paralysis has set in. The saliva at this period is very virulent, and many persons have caught the disease by putting their hands in a dog's mouth to relieve it of the supposed bone. The fierce biting and snapping at everything which eventually develops into furious rabies is merely the result of delirium.

Dr. Salmon declares that the popular belief that a mad dog dreads water is a fallacy; and he also disputes the truth of the universally credited opinion that the disease occurs only in the hot season. He brings forward statistics to show that there is little or no difference in the prevalence of the disease between summer and winter. He explains the well-known fact that the development of hydrophobia after inoculation varies in time from seven days to twelve months and longer, by the theory that the virus must reach the brain and spinal cord, and the bacilli multiply there before the whole system is infected; and that the virus of rabies does not spread through the system so quickly as many

other forms of infection. Another reason for this delay is probably to be found in the greater susceptibility of different individuals, and in the condition of their blood.

As a means of protection Dr. Salmon advises the destruction of wandering, worthless dogs, and the enforcement of a law providing for the muzzling, or leading by a chain, of the respectable members of the dog community. If these precautions could be considerately enforced, the writer believes that hydrophobia would be an extinct disease in a comparatively short time. His contention is certainly supported by the results obtained in cities, both here and in other countries, in which muzzling has been insisted upon.

QUARANTINE AGAINST CUBA NOT YET TO BE ABOLISHED.

While the latest reports are that only sporadic cases of yellow fever are occurring in Havana there should be no hurry in relaxing or in abolishing quarantine regulations regarding Cuban ports.

Health Officer Doty very properly advises against such premature action not only on the score that sufficient time has not elapsed to guarantee continuous immunity, but also on the safe principle that it is much easier and more reasonable to go on as we are going than to run the risk of changing plans and eventually being obliged to return to the original ones. There is no complaint that there is any burdensome restriction on our commerce with the West Indies as the time of detention is reduced to the minimum of safety with the additional satisfaction that the public mind is relieved from all apprehension of the possible admission of fever cases here.

So far as Cuba is concerned, it is gratifying to know that the sanitary improvements in and around Havana in tituted by the Army Medical Department have proved what can be done by cleanliness and proper hygienic methods along well recognized scientific lines. By these means, we are attacking the fever at its source and thus guaranteeing the safety of our own ports in the yellow fever belt Let us then take courage as the good work proceeds and be reasonably patient for radical and ultimate results.

News of the Week.

The Dallas (Texas) Medical College was recently made the Medical Department of Trinity University. At its commencement on June 18th there were eight graduates in medicine and two in pharmacy. Rev. P. M. Riley, of Cleburne, acting president of the university, conferred the degrees.

The Army Medical School.—The faculty of the Army Medical School, as newly constituted, is composed of the following members: Col. William H. Forwood, Assistant Surgeon-General, President of the faculty, *vice* Col. Charles H. Alden, retired; Col. Calvin de Witt, Assistant Surgeon-General, professor of military medicine; Major John Van R. Hoff, surgeon, lecturer on the duties of medical officers in war and peace; Major William C. Borden, surgeon, professor of military surgery, *vice* Col. Forwood, designated as President of the faculty; Major Frederick P. Reynolds, surgeon, as instructor in hospital corps drill and first aid to wounded, *vice* Capt. George D. DeShon, relieved.

The Hansen Memorial.—Prof. Rudolf Virchow has made announcement that the bust of Prof. Armaur Hansen will be formally unveiled on August 10. The ceremony will take place in the Lunggaards Hospital at Bergen, and a general invitation is extended to medical men throughout the world to be present at that time. Those intending to assist at the unveiling are requested to communicate with Dr. Sandberg in Bergen, Norway.

The Long Island College Hospital.—Plans are now being drawn for a new building to replace the main structure of this institution. The building will cost about $175,000, and of this amount nearly $125,000 has already been contributed.

Mr. Morgan's Gift to Harvard.—The new buildings for the Harvard Medical School, which are to be erected by Mr. J. Pierpont Morgan as a memorial to his father, are down on the plan as the administration building, anatomy, histology, and embryology building, and physiological chemistry building. These three buildings, it is expected, will cost about $300,000 each, and with the power house and the grading necessary will cost $1,020,000. The other two buildings of the medical school will cost about $250,000 each.

The New Tenement House Law which went into effect in this city on July 1, contains, among others, a provision that "no room shall be occupied for living purposes unless it shall have a window upon the street, or upon a yard not less than five feet deep, or upon a court or shaft of not less than twenty-five square feet in area, opening to the sky without roof or skylight, or unless such room has a sash window opening into an adjoining room in the same apartment which itself has a window opening on the street or on a yard not less than five feet deep, said sash window having at least fifteen square feet of glazed surface, being at least three feet high and five feet wide between stop beads and at least one-half thereof being made to open readily."

It also provides that no room in the basement or cellar shall be occupied for living purposes without a written permit from the Board of Health, that water shall be furnished in sufficient quantity at one or more places on each floor, and that the space underneath all sinks shall be left open.

Insurance Examiners' Societies.—The Association of Life Insurance Medical Directors, at its thirteenth annual meeting, held in Hartford, Conn., on May 28 and 29, elected the following officers: *President*, Dr. George S. Shepherd, of the Connecticut Mutual, Hartford; *First Vice-President*, Dr. Edward H. Hamill, of the Prudential, Newark, N. J.; *Second Vice-President*, Dr. Morris L. King, of the New York Life, New York; *Secretary*, Dr. Brandreth Symonds, of the Mutual, New York; *Treasurer*, Dr. Frank S. Grant of the Provident Savings, New York. *Executive Committee*: Drs. Edward Curtis, of the Equitable, New York; Oscar H. Rogers, of the New York Life, New York, and Granville M. White, of the Mutual, New York.

The American Association of Life Insurance Examining Surgeons, at its second annual meeting under the presidency of Dr. T. J. McGowan, at St. Paul, Minn., on June 3, elected the following officers: *President*, Dr. James H. Stowell, Chicago, Ill.; *Vice-Presidents*, Drs. James Hall Reed, Battle Creek, Mich.; Talbot Jones, St. Paul, Minn.; W. B. DeGarmo, New York City, and George Halley, Kansas City, Mo.; *Secretary* and *Treasurer*, Dr. T. A. Stevens, Caney, Kan.

The Medical Society of New Jersey.—At the annual meeting of this Society, held at Deal on June 25, 26,

and 27, the following officers were elected: *President*, Dr. John D. McGill, Jersey City; *First Vice-President*, Dr. E. L. B. Godfrey, Camden; *Second Vice-President*, Dr. Henry Mitchell, Asbury Park; *Third Vice-President*, Dr. A. W. Taylor, Beverly; *Corresponding Secretary*, Dr. E. W. Hedges; *Recording Secretary*, Dr. W. J. Chandler, South Orange; *Treasurer*, Dr. Archibald Mercer, Newark.

A Woman Teacher of Anatomy at Pavia.—Dr. Rina Monti has recently been appointed teacher of anatomy in the University of Pavia. She is a graduate of Pavia, and has already published several researches for which the gold medal of the university has been awarded her. She is a member of the German Anatomical Society. It is told of a former woman teacher in one of the Italian universities that she had to veil her face while lecturing because of her ravishing beauty.

The Plague is prevailing again in Alexandria and in several places in the interior of Egypt.

The Liverpool School of Tropical Medicine has despatched an expedition to Sierra Leone to determine the most practical and economical measures for the destruction of mosquitos. The sum of £1,000 and traveling expenses have been given by one contributor, and others have given oil, cement, chlorine compounds and fumigators for the killing of mosquitos. An instrument has also been devised by means of which an estimate can be made of the increase or decrease in the number of mosquitos. The expedition sailed for Africa from Liverpool the middle of June.

Professor Pietro Panzeri, whose sudden death from heart disease occurred in April 13th, just at the close of an active professional day, was perhaps the leading orthopedic surgeon in Italy. He was born at Sormano, in 1849, and after campaigning for a time with Garibaldi, he entered the Ghisleri College at Pavia, and later went to Milan, where his primary medical education was obtained. From the first, his chief interest was in orthopedic surgery. In 1884, he founded, in union with Prof. Margary, the *Archivio d'Ortopedia*, and continuedin editorial charge of the same up to the time of his death. He was also the first director of the orthopedic department of the Poliambulanza at Milan. When the Rizzoli Orthopedic Institute was projected at Bologna, in 1892, Panzeri was called to take the chief part in its construction and direction, and remained there until 1899, when he returned to Milan.

Resignation of a Lunacy Commissioner.—Mr. William C. Osborn, one of the three members of the New York State Commission in Lunacy, has sent his resignation to Governor Odell. Mr. Osborn was appointed a commissioner by Governor Roosevelt in April, 1899.

Association of American Medical Editors.—The annual meeting of the editors' association was held at St. Paul, June 3–5, 1901. A committee was appointed to amend the constitution and by-laws of the association by adding rules concerning the nature of the advertising which is to be admitted to the pages of the journals in affiliation with the association, these rules to be binding on all members. Among the papers read were "The Relative Value of Medical Advertising," by Dr. John Punton; "Improvements in Medical Education," by Dr. Dudley S. Reynolds; "Relation of the Medical Editor to Original Articles," by Dr. Harold N. Moyer; "Some Thoughts on the Ethics of Medical Journalism," by Dr. Burnside Foster. The association adopted resolutions favoring the establishment of a psycho-physiological laboratory at Washington, D. C. It also appointed a committee to draft a resolution requesting the directors of the St. Louis World's Fair to commemorate in a suitable manner the work done in medicine and surgery during the past century. The annual dinner was held at the Metropolitan Hotel on the evening of June 3d, President Stone acting as toast-master. The speakers of the evening were Drs. Love, Stone, Moyer, Matthews, Marcy, Fassett and Hall. The following officers were elected: *President*, Dr. Alex. J. Stone, of St. Paul; *Vice-President*, Dr. Burnside Foster, of St. Paul; *Secretary* and *Treasurer*, Dr. O. F. Ball, of St. Louis. The next meeting will be held at Saratoga Springs, N. Y., in June, 1902.

The Virchow Fund for Biological Research.—Some months ago, a committee consisting of Dr. Reed, President of the American Medical Association; Dr. Bowditch, President of the Congress of American Physicians and Surgeons; Dr. Weir, President of the New York Academy of Medicine; Dr. Welch, of Johns Hopkins University, and Dr. A. Jacobi, of New York, Secretary, published an appeal to the American Medical profession requesting contributions to the Virchow fund which was established ten years ago in honor of Rudolf Virchow's seventieth birthday, which was reached October 13, 1891. The fund was created for the purpose of fostering biological, anthropological and general medical research. A large German committee, with national committees formed all over the globe, has undertaken to increase this fund in honor of Virchow's coming eightieth birthday. The contributions must be sent to Germany on the 1st of September in order to be received by the Central Committee in due time. Therefore the American committee hopes that intending contributors will communicate with them before that date.

The Charities Exhibit at the Pan American Exposition, includes the entire exhibit of American charities at the Paris Exposition, with some additions. According to *Charities*, from which we obtain this information, the Parisexhibit was collected from representative institutions throughout the country, under the general supervision of the journal mentioned, thus presenting a comprehensive plan for the graphic study of relief agencies, hospitals and dispensaries, hospitals for the insane, and institutions for other classes of defectives, almshouses, State boards of charities, and other supervising and educational agencies. The exhibit includes also an extensive collection of books, bound reports and pamphlets on charitable and social subjects. Among the agencies that have supplied the most complete and interesting information for the exhibit should be mentioned the following: The New York State Board of Charities, whose exhibit includes photograhs of all the almshouses of the State of New York; the Boston Associated Charities, from which society there are, besides the typical case records, etc., two complete books of forms, photographs and other data showing methods of work; the New York Catholic Protectory, the Rochester Industrial School, the House of Refuge of Glen Mills, Pa.; the John Hopkins Hospital, Baltimore; and the Presbyterian Hospital of New York City. There are represented in all considerably over one hundred charitable institutions, several others having exhibits quite as valuable and as extensive as those mentioned.

Tuberculosis and Civilization.—Capt. E. E. Tilley, U. S. N., Governor of American Samoa, states that tuberculosis is becoming troublesome there, and he attributes its increase to the donning of clothing by the natives. In the old days, before the white men obtained control, the natives went nearly naked, protecting themselves from rain and dampness by liberal applications of cocoanut oil, which was quite as effective as the oily secretion of a duck's back in shedding water. Nowadays, the native man wears clothes

and no cocoanut oil, and when the clothes become wet, a cold follows, and in many cases tuberculosis results.

A Pan-American Quarantine Conference.—In accordance with the suggestion made at the third Pan-American Medical Congress in Havana, it has been decided to hold a conference of delegates from the American Republics regarding the institution of a uniform system of quarantine and the determination of measures best adapted to the suppression of yellow fever. From present indications, the United States Army Surgeons will have decided the latter question positively and finally before next February, at which date the conference will be held in Havana.

Proposed New Site for Philadelphia Almshouse and Hospital for the Insane.—The Department of Charities and Correction has after investigation decided to recommend to the Mayor the selection of Petty's Island as the best site for the almshouse and Hospital for Insane, which at present is connected with the Philadelphia Hospital. It is thought the site can be purchased for $500,000, and that suitable buildings can be erected and the entire work completed at a cost not exceeding $3,000,000.

Small-pox in New York.—There were over three hundred cases of smallpox reported to the Board of Health of this city during June. On one day last week there were seventy new cases.

A Medical Missionary Hospital in Chicago.—It is proposed to erect a new hospital and school building for the American Medical Missionary College in Chicago. The site favored is on the west side near the Cook County Hospital, and it is expected that the buildings will cost about $100,000.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the United States Navy for the week ended June 29th, 1901. June 24th—P. A. Surgeon E. M. Shipp detached from the *Michigan* and ordered to the Asiatic Station *via* vessel sailing from San Francisco, July 15th. P. A. Surgeon W. B. Grove detached from the Naval Hospital, Norfolk, and ordered to the *Michigan*, June 28th. Assistant Surgeon G. C. Smith detached from the *Vermont* and ordered to temporary duty on the *Alvarado*, July 1. Assistant Surgeon H. M. Tolfree ordered to the *Vermont*. June 25th.—Assistant Surgeon J. S. Taylor detached from the *Manila* and ordered to the Naval Hospital, Yokohama, Japan. Assistant Surgeon W. H. Bucher, commissioned a P. A. surgeon from April 15, 1901. Doctors R. T. Atkinson and A. W. Balch appointed assistant surgeons in the Navy from June 22, 1901. June 27th.—P. A. Surgeon R. S. Blakeman ordered to the Naval Hospital, Norfolk, Va.

A Society for the Study of Medical History has been established in Germany by an organizing committee consisting of Drs. G. W. A. Kahlbaum, of Basel, J. Pagel, of Berlin, and Sudhoff, of Hochdahl. The society will hold its first annual meeting immediately after the close of the forthcoming meeting of the Association of German Scientists and Medical Practitioners. The new society owes its existence to the abolition by the larger association of the section on the history of medicine.

New York News from Paris.—A Paris medical journal asserts gravely that the New York newspapers no longer speak of smallpox or any other disease that may happen at the time to afflict the inhabitants. The reason for this silence, according to our Paris authority, is that the Broadway merchants, not long since, held a meeting and drew up a circular which was sent to the daily papers, notifying them that if they published any more reports of the prevalence of infectious diseases in the city, they (the merchants) would at once withdraw their advertising patronage. "Since that time the journals have not breathed a word regarding publichealth, and if it were not for the official reports of the Board of Health, no one would know that there was any disease in New York."

A New Food Plant.—The United States consul-general at Frankfort-on-the-Main, Germany, quotes from some German papers a description of a plant growing in tropical Africa, belonging to the leguminous class, which is largely cultivated by the negroes as a food article. A French chemist, who recently analyzed the fruit or nut, found that it contained fifty-eight per cent. starch, nineteen per cent. nitrogenous matter, six per cent. hydrocarbon, four per cent. cellulose, three per cent. ash, and ten per cent. water. The plant is called by the African natives woandsu.

First Cousins May Not Marry.—The bill prohibiting the marriage of first cousins which was recently passed by the State Legislature became a law June 24, it not having been acted upon by the Governor within the specified time limit. It is stated that Pennsylvania is the eighth State to adopt such a prohibitory law.—*The Medical News.*

The Medical Society of the State of North Carolina.—At the annual meeting of this society, held at Durham, the following officers were elected: *President*, Dr. R. S. Young, Concord; *1st Vice President*, Dr. A. G. Carr, Durham; *2d Vice President*, Dr. I. M. Taylor, Morganton; *3d Vice President*, Dr. E. D. D. Carroll, Raleigh; *4th Vice President*, Dr. J. M. Parrott, Kingston; *Secretary*, Dr. G. W. Pressly, Charlotte; the *Treasurer* of last year was re-elected. The next meeting will be held at Wilmington in May, 1902. The same city entertained the society in 1892.

An International Invalids' Home in Spain.—It is reported in *El Siglo Medico* that an association of the charitably disposed in Spain are about to establish a home for persons unable to work on account of chronic illness. The institution will furnish accommodation for 2,000 invalids, 1,500 of whom must be Spaniards, while 500 may be natives of other countries.

Obituary Notes.—Dr. J. AUGUSTUS EHLER, aged eighty-one years, said to have been the oldest practicing physician in Pennsylvania, died on June 29th, at his home in Lancaster. He was a graduate of the old Pennsylvania Medical College in the class of 1841, an organizer of the Lancaster County Medical Society, and a member of the Pennsylvania State Medical Society and of the American Medical Association.

Dr. JOHN GARDNER, seventy years old, a retired physician, was found dead in bed in his room at the Broadway Central Hotel, in this city, on Saturday evening, June 29th. Death was due to disease of the heart, and was hastened probably by the heat. Dr. Gardner retired fifteen years ago. He had lived at the hotel for more than twenty-five years.

Dr. JOHN P. WHEELER, of Hudson, N. Y., died on June 28th, at the age of eighty-four years. He was a graduate of the New York University Medical School in 1843.

Dr. JOHN G. L. WHITEHEAD, of Bordentown, N. J., died suddenly on June 29th, at the age of seventy-three years. He was born in Philadelphia, and was graduated from the now extinct Philadelphia College of Medicine and Surgery in 1852.

Dr. CHARLES C. SAUNDERS, a dentist of Maidsville, W. Va., died in the Flower Hospital, in this city, on June 27th, from injuries sustained in attempting to board a moving street car.

Clinical Department.

TRAUMATIC HYDROTHORAX.

By J. M. FRANCE, M.D.,

PERRIS, CAL.

C. A., aged twenty-six, native of Sweden, was run over by a farm wagon, one front wheel passing over the left thoracic wall; there was no fracture of the ribs. The accident happened November 27, 1897. The man was under the care of a homœopathic physician from the date of the accident to March 24, 1898, when I assumed charge of the case. His condition at that time was as follows: pulse, 120; respiration, 56; temperature, 99°; apex beat of heart, one inch to the right of the sternum; the whole left thoracic cavity was dull from the clavicle to the diaphragm. A diagnosis was made of traumatic pleuritis, with effusion. I proceeded to aspirate, drawing out 480 c. c. of rose colored serum, but then cyanosis was so great that I ceased further efforts. From March 24 to April 5, I administered hydrogogue cathartics and diuretics, with little or no effect on the secretion of serum. On April 5, I again aspirated, this time taking out 2,160 c. c. of rose-colored serum, removing about half the quantity I thought the cavity contained. I continued the use of cathartics and diuretics with no preceptible effect on the accumulation of serum. On April 19, I again aspirated, this time taking out 4,480 c. c. of rose-colored serum, emptying the entire cavity, as I believed. Again on May 6, I was called upon to aspirate the fourth time, taking out 3,390 c. c., making a total of 11,510 c. c. of serum removed in the four operations. I saw the man in August, 1900, and there had been no return of the effusion, the lung had filled out completely, and the patient was enjoying his usual health and was able to do a full day's work.

AN UNTOWARD OCCURRENCE IN THE USE OF SUPRARENAL GLAND.

By CLEMENT BLOCH, M.D.,

NEW YORK.

The extract of the suprarenal gland is so much in use at present, that I think it my duty not to withhold from the profession a somewhat unpleasant experience I have had with it. A strong young man, professional singer, was operated on by myself last January for chronic empyema of the left antrum of Highmore and frontal cavities (Mikulicz' method). In March the secretion had completely ceased; but there was a strong adhesive band between the middle turbinated body and the septum (the result of a former nasal operation by another rhinologist) which had to be severed, as it not only interfered with the resonance of the voice, but began also to cause reflex disturbances (of an asthmatic nature). To prevent profuse bleeding I dusted a little suprarenal extract into the left nostril. I had done this repeatedly in this same case, without any ill result, but used this time a little more powder than usual. The following day my patient returned with complaints of headache and pain in the throat. On inspection I found œdema of the soft palate, particularly marked in the uvula, and congestion of both tonsils and lateral pharyngeal columns, most pronounced on the left side. The patient being anxious not to discontinue his professional duties, I made several minute incisions into the left tonsil and adjoining cellular tissue, a procedure which resulted in rapid depletion of the engorged tissues.

But for several days there were complaints of pains in the lateral columns and, a few days later, a (catarrhal) superficial round ulcer developed in the right tonsil (which had not been incised), but healed promptly under appropriate treatment. Four days later, a similar ulcer appeared in the left tonsil; this also healed promptly.

It seems almost certain that the described œdema and subsequent affection of the lateral columns and the tonsillar ulcers were due to the strong vasomotor action of the suprarenal gland, which had contracted the nasopharyngeal blood vessels to such an extent that venous stagnation resulted peripherally.

It might be argued that, in that case, the œdema ought to have been unilateral; but, when powder is blown through one nostril, some of it will inevitably get into the other also with the expiratory current of air; and there was, indeed, more marked congestion of the left side. Yet in this connection I must note a similar case (of pharyngeal œdema) which I saw six years ago at the N. Y. Policlinic. The patient, an anæmic young man, seventeen years of age, had apparently done nothing but spray his nose and throat with a mixture of benzoinol and Dobell solution (1:7) which I had ordered for his chronic rhinopharyngitis. I had to resort, in that case, to the hypothesis of idiosyncrasy. Still, in this present case, I think that too much of the suprarenal gland had been given, and I should advise that this substance be applied in aqueous solution.

149 West Ninety-first Street.

FOREIGN BODY LODGED FOR FOUR MONTHS THE TRACHEA OF A THIRTEEN-MONTHS' OLD CHILD.

By HARRIS F. BROWNLEE,

DANBURY, CONN.

The following case is worthy of note as an incident in general practice on account of the age of the child, the length of time which the foreign body had been lodged in the trachea, and the vague history which the case presented during that time.

While visiting another patient, I was casually asked to look at a baby nine months old. The mother said the child had been on the floor, and as a result had croup. The child, a bright little girl, seemed perfectly happy, but presented a slight rattle in respiration, and occasionally gave a little croupy cough.

In the morning she had had a coughing spell while on the floor, but it was not hard, and was not thought of sufficient severity to have been caused by the inhalation of a foreign body, although that possibility was spoken of at the time. She was cutting a tooth, which was nearly through, and the gum looked very irritated.

This condition continued for about a week, in spite of various medication for croup and cold. About that time, the tooth came through, and the throat seemed much better, though there was still a very soft rattle. With the advent of another tooth, the breathing became disturbed, and a harsh, croupy cough presented itself, which, however, subsided as soon as the tooth came through.

This continued for four months. I was unable to make a diagnosis. Other physicians saw the child during this time, but obtained no relief for her. The same soft rattle continued, with an occasional croupy cough. The opinion seemed quite general that the case was in some way influenced by the process of teething, but in this I could not wholly concur, although the child was decidedly worse at those times.

Finally, I saw the child again, just four months after my first visit; she was then thirteen months

old, rather anæmic, and did not look as bright and active as usual. She was suffering from marked dyspnœa, the inspiration being so labored as to hollow in the whole front of the chest. Expiration was not so much interfered with, but evidently there was a stenosis of the larynx or trachea which could no longer be treated expectantly, although the baby was then cutting a large double tooth.

Tracheotomy was advised, and, the consent of the family having been obtained, the child was taken into the Danbury Hospital. During the twenty-four hours preceding operation, the dyspnœa had steadily increased. Chloroform was administered, but when anæsthesia was only partially complete, the obstruction became total, and a rapid operation was at once necessitated. An incision was made down to and into the trachea through the cricoid cartilage, allowing exploration either upward into the larynx or downward into the trachea. The opening did not permit of the ingress of air into the lungs, but by carrying the incision a trifle downward, a stenosis of the trachea was exposed, in the center of which was a foreign body. After removing the foreign body, the stenosis was found so firm that no air could pass it, and it was necessary to carry the opening a little lower and put in a tracheotomy tube. The tube was left in place for two days, after which the stenosis was so far removed that air entered freely through the natural passages, and the external wound was allowed to close. The foreign body proved to be a flake of coal cinder, about one-quarter inch in width and one-half inch in length, and about the thickness of a finger nail, which had undoubtedly been inhaled four months previous, and had remained all that time in the trachea, at first causing very little trouble, but finally resulting in a complete stenosis by the inflammatory products around it.

The child made an uneventful recovery.

ON A FORM OF SARCOMA OF THE OVARIES AND ITS PECULIARITIES.

By W. Moser, M.D.,

Brooklyn, N. Y.,

Physician to the German Hospital.

There can be no question that fibromata and carcinomata of the ovaries are at times confounded both macroscopically and microscopically. In their gross appearance the œdematous fibroids have some resemblance to sarcoma. What one pathologist calls a carcinoma the other might designate sarcoma. In malignant neoplasms of the testicle the same difficulty arises.

The form of sarcoma of the ovaries here referred to is one presenting more clinical than microscopical differences. These are the following: The affection is bilateral, and starts in both ovaries at one and the same time, so that when examined grossly they exhibit a remarkable symmetry as to size and shape. They are uniformly smooth and of the same size, and are not lobulated as are fibromata of the ovary. They are not sarcomata engrafted upon pre-existing fibromata. The manner in which these tumors originate and develop speaks strongly against their parasitic nature.* Upon their removal metastases are very apt to develop; and not in the liver, as so frequently happens with carcinoma, but in the lungs as in sarcoma of the uterus, and especially sarcoma of bone and notably of the humerus.

Microscopically I have found them of the "mixed" variety, *i. e.*, containing small round cells, large round cells, and spindle-shaped cells.

In making the statement that metastases are more apt to occur in the lungs than in any other internal organ, I do not mean to imply that secondary sarcomata may not occur in the liver or secondary carcinomata in the lungs.

The clinical and microscopical pictures ought in all cases to be carefully associated. Cysts are more apt to form in sarcoma than in fibroma of the ovary. The growths in question are probably not the cysto-sarcomata of some authors. They (cysto-sarcomata) are usually unilateral, and form one large cyst or cystic mass, while these tumors contain only a few small cysts or none at all.

Calcareous masses are more apt to occur in fibroma than in sarcoma of the ovary, and could be confounded during life with osteoma or osteo-sarcoma originating in some bone in the pelvis or especially with a lithopedion.

* The parasitic theory of cancer is gaining ground, but more evidence is necessary to solve the problem. It is possible that some forms of sarcoma may be parasitic.

A CASE OF ANATOMICAL ASYMMETRY.*

By James E. Davis, M.D.,

Detroit, Mich.

The stigmata of degeneration as illustrated in the young child afford a most interesting study bearing upon the subject of heredity. On May 14th the writer attended Mrs. S. in her third confinement, the labor being normal and without incident excepting for a breech presentation and delivery.

The child presented the following asymmetrical form and development: Right foot.—There was one small supernumerary digit of soft cartilage formation, without nail, and of uniform size from base to distal extremity, with attachment at the side of the fourth phalanx of the little toe. Left foot.—This had a completely developed extra digit, slightly larger than the little toe, which was normal, and the attachment was on the side of the third phalangeal joint, the two toes being slightly webbed.

The right hand showed a well-formed supernumerary digit of the two distal phalanges. The third phalanx was wanting and attachment was a by fibrous band to the side of the little finger. The left hand had a completely developed extra finger attached similarly to the normal fourth digit.

The penis presented the appearance as if it had been circumcised, there being foreskin sufficient to cover only about one-fourth of the glans.

At the umbilicus three coils of intestines invested with peritoneum protruded on the lower side of the cord, forming a mass about the size of a goose egg. With a little persistent manipulation the mass was entirely replaced and the edges of the opening were accurately approximated with No. 3 catgut. The supernumeraries of the right foot and left hand were ligated and removed with the scissors.

The child, a boy, now eight days old, appears strong and well nourished, weighing eight pounds. The closure of the abdominal opening seems complete and strong.

The history gives no record of asymmetry in the family of either parent. The physical and mental development of the parents is rather poor.

831 Fort Street, West.

Book Reviews.

TUBERCULOSIS AS A DISEASE OF THE MASSES AND HOW TO COMBAT IT. By S. A. KNOPF M.D., New York. Awarded the International Prize, July 31, 1900. New York: M. Firestack, 1901.

THIS essay deserves wide dissemination among both the professional and lay classes. It contains an enormous amount of useful information in regard to the prevention of tuberculosis and the cure of its ravages, and it is written so that the layman will have no difficulty in understanding and carrying out the instructions Our greatest advances in the combat against tuberculous infection are evidently to be along the lines of prophylaxis, and works of this kind are therefore most valuable.

A TEXT-BOOK OF GYNECOLOGY. Edited by CHARLES A. L. REED, A.M., M.D., Gynecologist and Clinical Lecturer on Surgical Diseases of Women at the Cincinnati Hospital, etc. New York: D. Appleton & Co., 1901.

THE present volume adds another to the already somewhat overburdened literature of gynecology. The collaboration of a number of writers tends to increase accuracy in discussion and broadness of treatment in the different departments of a subject, so that, in this regard, the present work may be considered a success. A number of well-known writers on gynecological subjects and subjects relating to gynecology have contributed a systematic series of articles which are arranged as if the volume were written by one man, and as if he had desired to offer a treatise on gynecology arranged on the usual plan of such works. The illustrations are numerous and excellent, many of them clearer and better than is usual in such books, and under each there is a short explanatory paragraph. The special diseases of the female urinary organs, and the diseases of the rectum are considered in chapters at the end of the book, and though such subjects are not strictly gynecological, their consideration seems advisable in works of this kind. It seems unnecessary to pick out chapters for special commendation, but that on neoplasms of the uterus, and that on disorders of menstruation might be so noted. The general make-up and appearance of the book is good, and it will undoubtedly prove a satisfactory work of reference.

CLINICAL PATHOLOGY OF THE BLOOD. A Treatise on the General Principles and Special Applications of Hæmatology. By JAMES EWING, A.M., M.D. Professor of Pathology in Cornell University Medical College, New York City. Philadelphia and New York: Lea Brothers & Co., 1901.

IT is only within recent years that the blood has been considered as having a special and distinct pathology of its own, and therefore the special literature of the subject is modern. Much of this literature is American, and the present volume is a creditable addition to previous works. The author's plan has been to write a working manual upon pathological conditions in the blood, embodying an epitome of the subject up to the present time, arranged and amplified according to his own ideas. After a chapter or two devoted to blood examination and analysis, which are well written and practical, the author takes up in order the various diseases accompanied by changes in the blood, describes and illustrates these changes, and discusses their significance. Four chapters are devoted to an excellent description of the different phrases of the malarial organism. The illustrations which are drawn by the author are very satisfactory, and the bibliographical notes are encyclopedic in their thoroughness.

APHORISMS, DEFINITIONS, REFLECTIONS AND PARADOXES: Medical, Surgical and Dietetic. By A. RABAGLIATI, M. A., M. D., F. R. C. S. Ed., Late President of the Leeds and West Riding Medico-Chirurgical Society, etc. New York: William Wood & Co. 1901.

THE author of this entertaining book has some peculiar ideas on the subject of eating which he has previously expressed in his "Air, Food, and Exercise," and which he expounds at much greater length in the present work. He believes, and in this he is not exceptional, that much illness in the world is the result of overeating, but he goes further than most persons in his concrete application of this belief, even giving a list of more than fifty diseases and complaints due to what he calls "poly-siteism" and "pollaki-siteism," or, in other words, overeating, by which he means the ingestion of more than 24 ounces of mixed food in the twenty-four, or the taking of the same or a smaller amount in more than three meals a day. He is a regular Dr. Tanner in his liking for fasts, and glibly recommends a six weeks' abstention from food as a sovereign remedy for many ills. We venture to say very few could be found who would go with the author to the lengths he recommends, but there is much sound sense in his aphorisms, and if he can persuade his readers to pay more attention to the diet of their patients, he will have done a good work. The book is worth reading, for it is the production of an original thinker.

DIET AND FOOD, Considered in Relation to Strength and Power of Endurance, Training, and Athletics. Third Edition. By ALEXANDER HAIG, M. D. Philadelphia: P. Blakiston's Son & Co., 1901.

THIS is a little 16mo, booklet of 109 pages, and may be considered as a sort of supplement to the author's larger treatise on uric acid, which has had such an extensive circulation among the profession. Haig's views are well known. He regards an excess of uric acid in the system as the *fons et origo* of nearly every complaint (not contagious), either acute or chronic, that afflicts humanity, and he here lays down the rules of diet that in his opinion are best calculated to prevent or reduce this excess. Unfortunately his premises do not always seem to accord with the present teachings of science, and his calculations are not always warranted by his premises. There is much in the book that appears to be sound and judicious, but then again much more that should not be accepted too implicitly.

THE EXTRA PHARMACOPŒIA. By WILLIAM MARTINDALE, F. L. S., F. C. S., Late President and Examiner of the Pharmaceutical Society, and W. WYNN WESTCOTT, M. B. Lond, D. P. H., H. M.'s Coroner for Northeast London. Tenth Edition. London: H. K. Lewis, 1901.

WE have several times had occasion to commend the successive editions of this remarkably useful work, and can now do little more than repeat what we have said before. We know of no book so convenient for reference on all subjects relating to drugs and their therapeutic uses as this. We have it in constant use, and seldom are we disappointed in not finding in succinct form all that is necessary to be known about any drug, official or not, used in medicine. The preface to this edition, in recounting the new drugs in the different classes which have come into use since the ninth edition was issued, presents us with a striking review of the progress in materia medica of the closing years of the nineteenth century. At the end of the book is a useful therapeutic index.

MENTAL DISEASES AND THEIR MODERN TREATMENT. By SELDEN HAINES TALCOTT, A. M., M. D., Ph. D., Medical Superintendent of the Middletown State Homœopathic Hospital in Middletown, N. Y.; Professor of Mental Diseases in the New York Homœopathic Medical College and Hospital. New York: Boericke & Runyon Co. 1901.

DRAWING from the vast experience of twenty-five years' work among the insane, the author has given to the profession a series of graphic pictures of the various mental disorders which are commonly met. His classification is modern and his philosophy good. Throughout the work he lays special stress upon the important points, fearing confusion in teaching the rare and non-essential. He advocates the "hospital method" of treatment as opposed to the older "asylum" process of allowing the disease to take its own course with no special mental or other therapeutic measures to supplement restraint.

CHRONIC URETHRITIS OF GONOCOCCIC ORIGIN: By J. DE KEERSMAECKER, Chiefof Service, Diseases of the Urinary Organs at the Centraalklinik of Antwerp, and J. VERHOOGEN, Agrégéat the University of Brussels; Chief of Service, Diseases of the Urinary Organs, at the Polyclinique Libre. Translated and edited with notes by LUDWIG WEISS, M. D., Attending Physician to the Gento-urinary and Skin Service, German Poliklinik; Dermatologist to the Hebrew Orphan Asylum, New York; etc. New York: William Wood & Co., 1901.

THE main object of this work is to teach the profession the value of urethroscopy as a means of diagnosis and treatment in Genito-urinary disease. The authors claim with apparent truth that if one patiently studies the urethral canal with direct means of observation the whole subject becomes clearer and the treatment more successful. The danger of being discouraged by not studying the subject sufficiently long is acknowledged, and yet the advantages to be gained cannot be overestimated.

To facilitate this method of research the authors have given very complete descriptions, accompanied by several excellent urethroscopic pictures in colors. The book is divided into three parts, the first of which treats of the

anatomico-pathological study of the subject; the second, its diagnosis, and the third, its treatment.

Dr. Weiss, in order to complete the subject, has added chapters on the Palpation and Expression of Cowper's, the Prostate, and the Seminal Glands, on Urethral Asepsis, and on the Relations of Gonorrhœa to Marriage.

The work is one which can be highly recommended as authoritative, instructive, and interesting. The type is excellent and the illustrations very useful.

Die Cystitis, von Karl Ritter von Hofmann. Vienna. 1900.

This modest brochure of eighty pages might be a chapter in an exhaustive treatise on genito-urinary diseases. It is the work of a writer who strives to teach, and to do so with a profound consciousness of the responsibility he incurs in the desire to communicate his knowledge to others. The little book throughout is written with painstaking detail. No step of technique is deemed too small for careful explanation. Throughout, the work reveals that the author is a student of English, for each of his German sentences is brief, telling a single fact in an unimbricated manner. In this, von Hofmann's writings call to mind those of Posner, Kollman, and Wossidlo, who have shown that scientific German can be written in a style which permits of ready comprehension. How fully the subject is treated is manifest by the fact that von Hofmann describes even the stains which the remedies employed may make upon the patient's skin and garments; he shows how they may be avoided and how removed. In one instance, and the only one in the book, the author opens the way to criticism when he says that intravesical irrigation is a possible cause of cystitis. Had he insisted that these irrigations, *if not cautiously performed*, may cause traumatism of the mucosa of the bladder, then the argument would certainly have a place. The book is up to the very latest conceptions of cystitis, and the author's treatment of his subject is so intensely practical as to make the book indispensable to any specialist's or even general practitioner's library.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. A New Edition, Completely Revised and Rewritten. Edited by Albert H. Buck, M.D. Volume II. New York: William Wood & Co. 1901.

The second volume of this great encyclopædia contains the titles "Blastoderm" to "Chloraloximes." The most important of the articles are "Blood," "Blood Stains," "Bloodvessels," "Brain" (320 pages), "Breast," "Bubo Plague," "Camp Diseases," "Cancer" and "Carcinoma," "Cataract," "Cerebrospinal Meningitis," "Cestoda" and "Chest." There are seven hundred and sixty-five half-tone and wood engravings and eleven chromolithographic plates in the volume. There is little that can be said in a notice of a work of this nature, for any critical review would of necessity deal, not with the volume itself, but with the individual articles it contains. These naturally vary greatly in importance, length, and mode of treatment, some being excellent in every respect, others erring somewhat on the side of too great condensation or on that of prolixity. In general, however, the length of the individual articles varies quite uniformly with the importance of the subjects, thanks to the good judgment of the accomplished editor. The articles on health resorts, mineral springs, and materia medica especially are models of their kind, brief, yet filled with exactly the information desired by the consultor. Without disparagement to the first edition, which is still a mine of information and a most valuable possession, it must be said that this second edition, judging from the two volumes now published, is so far improved and extended as to constitute almost a new work. It is one that will be, as its predecessor was, indispensable to the medical practitioner who would keep himself abreast with the times.

A Text-Book of the Practice of Medicine. By Dr. Herman Eichhorst, Professor of Special Pathology and Therapeutics and Director of the Medical Clinic in the University of Zurich. Authorized Translation from the German. Edited by Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic. Two volumes. Philadelphia and London: W. B. Saunders & Co. 1901.

At the present day, the medical world does not look for its inspiration and instruction in any such measure as it formerly did to German sources. This is, however, not because the Germans have fallen behind, but because the other nations have forged ahead. The great medical discoveries of the latter quarter of the nineteenth century were not exclusively or even preponderatingly German, but were English, American, French, Italian, and Spanish as well. Nowadays the label "made in Germany" is not the necessary hall-mark of medical ware, and no book or discovery or drug is accepted unquestioned because it has originated in central Europe. Eichhorst's work, therefore, will be judged on its merits, as it may compare with the books published originally in our own or other tongues, and cannot hope for the commendation "sight unseen," as children would say, which Niemeyer's treatise received a generation ago. It has no reason, however, to fear a judgment of this kind, for its intrinsic merits are sufficient to commend it anywhere. Professor Eichhorst is an accomplished clinician and teacher, and he has written an orderly treatise which cannot fail to instruct any one who consults or studies it. Each subject is treated of thoroughly in all its aspects, but it is especially in the sections on diagnosis and treatment that the author is at his best. The editor's notes are lucid and not too numerous. The translation is fairly smooth, but we regret to see that the translator has adopted the ugly style of apocope affected in Philadelphia—the Gould hiccup, we believe it is called. The illustrations are hideous, but that may be the fault of the Zurich type of physiognomy, as many of them are pictures of the author's patients at the Zurich clinic. As a whole, the work is one that can confidently be recommended as a trustworthy guide, and it will be welcomed as a worthy addition to the already long list of treatises on the principles and practice of medicine.

An Index of Symptoms as a Clew to Diagnosis. By Ralph Winnington Leftwich, M.D., Late Assistant Physician to the East London Children's Hospital. Second Edition. New York: William Wood & Co., 1901.

This little volume, a pioneer of its kind, will prove of value not only to advanced students, but to practitioners as well, for in it they have a ready index for the various diseases which must be considered in making a diagnosis. It is not intended to supersede descriptive symptomatology, but rather to refresh the physician's memory when dealing with obscure conditions, and to give him a list of possible explanations for diagnostic purposes.

A Handbook of Materia Medica, Pharmacy and Therapeutics, Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, and Minute Directions for Prescription Writing. By Samuel O. L. Potter, A.M., M.D., M.R.C.P.Lond., Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; Author of the "Quiz Compounds of Anatomy and Materia Medica," "An Index of Comparative Therapeutics," etc.; Late Major and Brigade Surgeon of Volunteers, U. S. Army. Eighth Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co. 1901.

A book which has passed through seven editions in thirteen years is evidently one which has met and continues to meet a want, and needs no word of commendation from the reviewer. Successive editions of a work of this kind do not usually differ much from those which have preceded them, except in the inclusion of some new drug, the utility of which has been demonstrated, or the dropping of some worthless and unused remedy from the list. This edition, however, has benefited by the author's residence for two years in Manila, and contains considerable new material gathered from his experience in tropical medicine. A useful feature of the book is a table of apothecary's and metric weights and measures in parallel columns, placed for convenience of reference on the inside of the front cover. A thumb-index enables one to turn at once to any of the sections in the book. In many respects this is one of the best books on therapeutics that is published in the English language, which means in any language, for this is the branch of medicine in which the English and Americans easily excel.

Transactions of the Medical Society of the State of New York, for the year 1900. Published by the Society.

Besides the usual report and anniversary address by Willis G. Macdonald, of Albany, there are many excellent papers, among which may be mentioned the State Care of Tuberculosis Patients, Prophylaxis in Gynecology, and investigations into the Causes of Cancer. The latter is by Roswell Park.

Manual Teórico y Práctico de las Enfermedades de la Nariz y de sus Senos Accesorios. Por el Professor Ramón de la Sota y Lastra. Sevilla: Escuela Tipográfica Salesiana, 1800.

This manual forms Vol. I. of a system entitled "Enfermedades de la Nariz, Boca y Garganta," intended to cover the entire field of rhinology and laryngology. It is written by one of the very few Spanish specialists in this field

whose names are known outside of their own country, and shows that the author is fully abreast of the times in all that pertains to these special departments of medical practice. The present work covers familiar ground, is concise, well illustrated, and will undoubtedly prove of much service to the author's fellow countrymen and to medical practitioners in Latin America.

CHLOROFORM: A Manual for Students and Practitioners. By EDWARD LAWRIE, M. B., Edin., M. R. C. S. Eng., Principal of the Hyderabad Medical School, etc. London: J. & A. Churchill. Philadelphia: P. Blakiston & Co. 1901.

THIS brochure contains considerable useful information on chloroform, its action, dangers, and use, and the writer makes out a good case for this anæsthetic under proper precautions, which he details. Chloroform has certain advantages not possessed by any other drug used for the same purposes, and if we can avoid certain dangers which it also has, we will perhaps have an ideal anæsthetic. Consequently anything which adds to our knowledge of the subject is worth while.

LES FEMMES DOCTEURS EN MÉDECINE DANS TOUS LES PAYS: Etude Historique Statistique, Documentaire, et Anecdotique sur L'Art de la Médecine Exercé par la Femme. Par HARYETT FANTANGES. Paris: Alliance Coopérative du Livre. 1901.

THIS is a statistical catalogue of the names, nationality, characteristics and other facts relating to women in various parts of the world who have graduated in medicine. The historical material in the volume is the most interesting.

THE TRANSACTIONS OF THE SOCIETY OF ANÆSTHETISTS. Vol. III. London: The Medical Publishing Company, Limited. 1900.

THIS is the latest report of the Society whose object is explained by the title.

DIE PELLAGRA. Von Prof. Dr. V. BABES in Bukarest und Prof. Dr. V. SION in Jassy. Wien: Alfred Hölder. 1901.

THIS is the second half of the third part of Volume XXIV. of Specielle Pathologie und Therapie by Nothnagel. In a monograph of eighty odd pages with two full-page plate illustrations, the authors have presented a most complete account of this interesting disease, beginning with its history, geographical distribution, and statistics and closing with a full bibliography. There are eight illustrations in the text. The chapters on predisposition, on the influence of certain articles of diet, especially spoiled grain, on so-called sporadic pellagra, and on experimental pathology are of especial interest. The pathological anatomy with reference to skin and nerve lesions and visceral changes has been very carefully worked out.

DIE LEPRA. Von Dr. VICTOR BABES, Professor der Pathologischen Anatomie und Bacteriologie an der Universität, Bukarest. Wien: Alfred Hölder. 1901.

THIS work of 340 pages forms a portion of Volume XXIV. of Nothnagel's special pathology and therapy. It is freely illustrated, containing 66 cuts in the text and ten full-page plates, eight of which are colored, and of exquisite workmanship, giving the clinical features of various forms of leprosy. The author bases his work upon a large material observed in Roumania and treats his theme in the light of modern advances as reflected in the work of the Berlin Lepra Congress and the large literature which it called forth. All phases of the question have been entered upon and the result is the presentation of a valuable addition to our knowledge of a most important subject.

Delirium Tremens.—A. Elzholz says that, after the chronic abuse of alcohol toxines similar to those of pneumonococci and other bacteria are formed in the body. If abstinence ensues, or the resistance of the organism be lowered through infectious diseases or otherwise, the poisons, which until then were combined, are set free and delirium results. Abstinence, therefore, assumes great importance in the production of delirium. If, during the use of alcohol, delirium ensues it is because the amount of alcohol taken was insufficient, and there exists a relative abstinence with the elimination of a great amount of toxic substances. In fifty per cent. of the delirious cases in which there exist meningal and bronchial inflammation toxiæmia is at the basis of them.—*Wiener Klinische Rundschau.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, June 27, 1901.

Some Forms of Intestinal Obstruction, Due to Adhesions.—A. J. Cabot reports several cases in which the functional activity of different parts of the alimentary canal has been interfered with as the result of extensive adhesions. Partial twists and kinks in the bowel are prevented from untwisting by these adhesions, which tie them to the parietal peritoneum. The symptoms of obstruction are usually not constant, as the bowel contents can pass through the partially obstructed coil. Overloading, or interference with peristalics by neighboring inflammaton, however, may produce all the symptoms of an acute stoppage. The seat of obstruction in the cases seen by the author have been in the ileum or in the sigmoid flexure. At both of these points we have a movable portion of the intestine running into a more fixed part—the ileum into the cæcum and the sigmoid flexure into the rectum. This relation of a movable to a fixed portion is favorable to the production of the form of obstruction under consideration. The author studies the mechanism of the obstruction and describes his cases.

Catharis in Abdominal Surgery.—L. R. G. Crandon comes to the conclusion that: 1. In acute pelvic peritonitis both enemata and drugs by mouth should be used to produce catharsis before operation, drugs by mouth and oil enemata after operation. 2. In all acute inflammatory conditions of the abdomen where the alimentary tract is involved, the bowels should be moved by enemata alone, before and after operation, the enema of salts, turpentine and glycerine being the best.

Medical News, June 29, 1901.

The Importance of a Recognition of the Significance of Early Tuberculosis in Its Relation to Treatment.—E. L. Trudeau declares that the results obtained at sanatoria have demonstrated not only that the disease is curable, but that it is curable in direct proportion to the stage at which the treatment is applied. Persistent slight cough, with loss of flesh and strength, a slight afternoon rise of temperature of one-half to three-quarter of a degree, and constant lassitude, are symptoms which, even without any appreciable signs on physical examination, point in many cases to incipient tuberculosis. Search for the bacillus should be begun early and persisted in as long as there is any doubt as to the diagnosis. The microscope has been of invaluable aid in the diagnosis of tuberculosis, but the absence of the bacillus from the expectoration is not necessarily a conclusive criterion. In the great majority of cases and consideration of the history of the case and a careful study of the rational signs with a thorough physical examination of the chest, and a microscopic examination of any sputum obtainable, aided by and careful X-Ray examination of the patient when required, will enable the physician to make an early diagnosis. The tuberculin test is not often necessary, but its value lies in the fact that it is most applicable, and will, demonstrate the presence, and give corroborative evidence as to the absence of a tuberculous process in the body in just that class of incipient cases where the usual methods of diagnosis fail. Early diagnosis of this dread disease is all-important.

Cutaneous Manifestations in Diabetes.—S. Sherwell first mentions the generalized xeroderma which prevails in the large majority of cases of diabetes. It causes great discomfort and is generally attended with generalized pruritis. The mucous secretion in those cases of the upper air-passages and mouth is gummy, and lies in distinct ridges. Pruritus alone being present in an individual without apparent cause should excite suspicion of diabetes. Eczemas occurring in any region of the skin, but most often on the flexor surfaces, and which are generally attended by the fiercest itching, should also call for careful examination of the urine. The urine often varies at different hours of the twenty-four, so that examination of the morning water is not sufficient. Cleanliness and antiparasitic lotions are the best treatment. Bichloride of mercury, about 1-1000 in a dilute emulsion of bitter almonds, which may also contain a moderate amount of salicylic acid, and resorcin is very valuable. Furuncular and carbuncular manifestations are often concurrent, and are clearly caused by the diabetic state. Erythematous lesions, some evanescent, others as erysipelas, are sufficiently common as a result of this glycosuric state, and also gangrene. Dermatitis herpetiformis or Duhring's disease, is often seen in diabetes. Xanthoma diabeticorum and possibly blastomycetic dermatitis are originated by the diabetic diathesis. Glycosuric urine is sometimes found in infants, on account of the liberal character of the nutrition. Diminution of

the diet, with attention to other conditions, has greatly simplified the treatment and advanced the cure of eczematous and other diseases, and at the same time has caused the total disappearance of the glycosuric character of the urine.

American Medicine, June 20, 1901.

The Hallucinations of Digitalis.—Does Digitalis Cause Hallucinations, Delirium, or Insanity Under Certain Conditions?—Harry Orville Hall describes the illness of a woman between thirty and forty years of age, the curious mental features of the illness being apparently due to digitalis, which was administered. The patient was of robust build, and naturally of an unusually happy and cheerful disposition. The sickness described was at the time attributed to some derangement of the liver. After several weeks she began to have strange hallucinations. The whole course of the illness was so singular that the writer suspected some drug might lie at the bottom of the trouble. There was no other satisfactory explanation. The author, in looking up the literature on the subject, found that Darogiez had observed no less than 20 cases, where delirium followed the administration of digitalis.

Prevention of Disease Infection by Micro-organisms Through the Mouth and Nasal Cavities.—Robert Rayburn states that a mouth filled with decayed teeth is always in a septic condition. The septic fluids therefrom are being continually swallowed and passed into the stomach which together with the intestinal canal, they aid in infecting. Thus result many cases of chronic dyspepsia and gastro-intestinal catarrh. Such patients should have the mouth put into perfect condition by the dentist. Mouth breathing is always a symptom of disease. Chronic enlargement of the tonsils being one of the most frequent causes of this condition, requires prompt and thorough treatment, and in most cases these organs should be removed. The same treatment applies also to adenoid and polypoid growths in the posterior nasal spaces and pharynx. Patients should be advised to use the tooth brush and cleanse the teeth with some mildly antiseptic solution three times a day. A dilute solution containing glyceriol of carbolic acid, listerin, or campho-phenique will do what is required. For a tooth powder there is nothing so good as precipitated chalk. Many authorities believe that the regular and systematic cleansing of children's teeth would not only prevent decay of the teeth but would greatly diminish the number of cases of scarlet fever, diphtheria, measles, tuberculosis, typhoid fever and all the other infective diseases which kill so many of our children every year.

Deutsche Medicinische Wochenschrift, June 13, 1901.

Contributions to the Subject of Immunity.—V. E Mertens undertook to prove for cholera serum conclusions that R. Pfeiffer years ago formulated for typhoid sera, viz., that the specific bacterialisms and agglutinating bodies behaved differently on keeping, the latter depreciating markedly in strength even when every precaution for their preservation is taken. The cholera sera available had been kept on ice for five years and the tests showed that the immune bodies are far more resistent to decomposition than the agglutinating substances, and a further proof is thus afforded of their being entirely distinct bodies. A second research was undertaken to determine whether the direct injection of immune bodies into the blood gave a stronger reaction than the simple subcutaneous administration. For the experiments virulent agar cultures of cholera vibris were sterilized and tested on rabbits. The results showed that by intravenous injection the activity of the serum was from twenty to one hundred and fifty times as great as by the subcutaneous method, a result in accord with the behavior of ordinary drugs administered in these two ways.

A Case of Intestinal Necrosis of Questionable Etiology.—L. Bornhaupt reports a case which is interesting owing to its obscurity. The patient, a man of twenty-two years, was suddenly seized with pain in the abdomen, vomiting and constipation. Purgatives did not act, and for two days the condition grew worse; the face became cyanotic, respiration labored and the pulse feeble. There were no tympanities, abdominal tenderness or localizing signs, and death occurred one hour after admission to the hospital. On autopsy, an area of necrosis was found on the ileum, beginning a short distance above the cæcum and extending upwards for about four inches.

Below there was a sharp line of demarcation, but upwards the gangrenous portion merged insensibly into the deeply congested mucosa above; the right ingunial ring was dilated. All the organs were deeply congested, and the right pleural cavity contained a blood clot twice the size of the fist, compressing the lung against the spinal column. The author's theory is that possibly the necrosis was due to a hernial incarceration which subsequently reduced itself, while the immediate cause of death was the hemorrhage into the pleura. The possibility of embolism of the mesenteric vessels must also be thought of, as this produces conditions closely resembling those of occlusion.

The Connection Between Sclerosis of the Coronary Arteries and Diseases of the Heart Muscle.—Th Neuburger has found that in thirty-eight cases in which he has made the diagnosis of angina pectoris the autopsy revealed the existence of calcification of the coronary arteries, and is of the opinion that the vascular lesion is always the causative factor of the disease. The symptom complex, known as angina pectoris is only a part of a more extensive affection which presents, in order of development, stages of disturbed sensation, disturbed motility and disturbed nutrition. During the first period pain in the cardiac, sternal or gastric regions, which radiates to the left shoulder and arm is observed. This is usually produced by walking or exertion and subsides on rest, it is particularly marked when the stomach is full, and may be barely perceptible to the patient, or run the gamut up to extreme anguish with the sense of impending dissolution and syncope. The second stage is marked by diminished heart power, and shows itself by shortness of breath, lassitude and weakness, while in the third period sudden nocturnal attacks of pain and dyspnœa, with feeble, irregular heart action appear. The treatment is that of heart disease in general; all exertion is to be avoided; amyl nitrate, small sub-cutaneous doses of morphine or sodio-salicylate of caffeine and strophanthus are to be recommended, while glonoin and potassium iodide are less useful. Diuretin works well in combatting the œdema, and powdered digitalis often relieves the asthmatic attacks.

Berliner Klinische Wochenschrift, June 10, 1901.

The Dietetic Treatment of Epilepsy.—R. Balint, carrying out the theories of Toulouse and Richet, treated twenty-eight epileptics by removing as nearly as possible all the sodium chloride from their diet and replacing it by the corresponding bromine salt. After some experiment the following dietary was formulated and used throughout: one to one and a half liters of milk, forty to fifty g. of butter, three eggs and three to four hundred g. of bread and fruit. The bread was specially prepared by baking it with three of g. sodium bromide and no salt. On this diet the patient receives only about two g of sodium chloride and unconsciously takes three g. of the bromide daily. In all cases the results were highly satisfactory, the frequency and intensity of the attacks were reduced, the mental condition was improved and the general health rapidly appreciated. No signs of bromism ever developed, and the rationale of the method seems to lie in the fact that the sedative action of the bromide is in this way greatly enhanced. The treatment should be tried in all cases, and is most advantageously carried out in institutions where the usual beneficial effects of a regulated daily life can also come into play.

A Case of Hemorrhage from the Internal Carotid following Cholesteatoma.—Heine's patient was a woman of fifty-six who had all her life been suffering from middle ear disease. Shortly after coming under observation a radical mastoid operation was done, and six months later a second similar operation was performed. At this time a large part of the anterior and inferior tympanic wall was removed and a non-pulsating cord the size of a quill was exposed in the anterior angle of the cavity. Four days later in changing the dressings a stream of dark blood suddenly poured out of the wound, but the bleeding could be checked by packing. Nearly a month after operation, a second severe hemorrhage took place and two days later during the momentary absence of the nurse, the patient got out of bed, which indiscretion was followed by instant and appalling hemorrhage. Taken at once to the operating room and anæsthetized the site of bleeding was exposed and firm packing applied successfully, but four days later death resulted from œdema of the lungs. The autopsy revealed the fact that the internal carotid was eroded at its angle in the carotid canal, the vessel being considerably thickened for some distance above and below and its lumen diminished, which accounts for the absence of pulsation noted during the operation.

Is Carcinoma Curable?—A Adamkiewicz answers this question in the affirmative, and goes so far as to say that the problem of providing a remedy has found a scientific solution. The case upon which he bases his conclusions is that of a woman of fifty-eight, who, for several years, had presented the usual clinical picture of pelvic carcinoma involving the uterus, vagina and parametrium, which had advanced so far that serious rectal and vesical symptoms developed, and when the patient presented herself for operation, an eminent authority (Albert) declared the condition inoperable on account of the imminent danger of a breaking through of the growth into bowel and bladder. As a last resort, therefore, the medi-

cal attendant injected the author's "cancroin" with almost immediate effect. The bleeding stopped, the pain abated, and the patient rapidly gained strength, so that she was able to leave her bed and attend to her household duties. Now, one year after she had been given up as hopeless, she feels as well as ever, and is leading an active life, has no bleeding, pain, rectal or urinary symptoms, while examination shows that the formerly vigorously vegetating growth has been transformed into an apparently inert and cicatrized mass which distorts and enlarges the uterus, but is not painful or ulcerating.

Gelatin as a Hemostatic.—H. Gebele reports two cases of epistaxis and one of bleeding from a tooth socket in a hemophiliac which could not be controlled by ordinary means, and were successfully treated by the use of gelatin solutions. Two of the patients made a perfect recovery, but the third succumbed to a double lobar pneumonia, which was rapidly fatal, owing to the fact that the patient had been bleeding for over a week before coming under observation, and was consequently highly anæmic. In conjunction with these clinical observations, some experiments were made on dogs and rabbits with the following conclusions: A considerable loss of blood favors the absorption of gelatin solution, which in turn increases the natural coagulability of the blood. If the preliminary hemorrhage has been but small, the action of the gelatin will be inadequate, which explains some of the discrepancies reported by different authors after a trial of the method. To be efficacious, a loss of a fifth to a fourth of the total blood must have preceded the introduction of the gelatin, which conditions usually obtain in practice when the patient is mostly already exsanguinated when he is brought for treatment. In such cases gelatin solutions of a two per cent. strength for subcutaneous and a ten per cent. strength for local use are very serviceable, while in less serious bleeding the usual chemical, thermal, and mechanical measures suffice.

The Hot Air Treatment of Chronic Middle-Ear Disease.—Hecht reviews the various plans which other writers have advocated for the introduction of ordinary and heated air into the tympanum, and states his own belief that Holländer's apparatus for the application of hot air in skin diseases, provided with suitable aural pipettes, affords the most convenient instrument. The ear speculum is held with one hand and the hot air pipette is introduced and turned in various directions with the other, while the patient himself manipulates the bellows. By this means both of the operator's hands are left free, and all danger of burns is obviated since the patient is instructed to stop working the apparatus as soon as he feels any pain. In a disease like this, for which no average normal course exists, it is impossible to draw satisfactory conclusions, but the writer believes the method does good, and explains the favorable results as being partly direct and partly indirect. In the first place, the hot air rapidly overcomes the macerated condition of the tympanic mucosa, and furnishes a dry cavity in place of the moist chamber so favorable to bacterial growth, and in the second place, the hyperemia so produced is indirectly beneficial through the increased blood supply it entails, since the nutrition of the tissues is thereby greatly favored and the powers of resistance augmented.

French Journals.

A New Physical Sign Characteristic of Alcoholic Intoxication: "The Sign of Quinquaud."—Ed. Aubry reports this sign as described by Quinquaud: The individual is ordered to separate his fingers, and while extending them, he presses them firmly in a perpendicular direction against the palm of the examiner's hand. During the first two or three seconds nothing in particular is noticeable, but soon a series of slight shocks is felt, as if the bones of each finger struck each other successively, finally reaching the palm, against which the finger tips are resting. The crepitation varies in intensity according to the nature of the individual. It is more marked in men than in women. The pressure of the fingers should be moderate. This sign has not been found in epileptics nor in general paralytics. It has been noted only in alcoholics. Although sufficient work has not been done on this subject to make possible very sweeping assertions as to its value, nevertheless, in all cases in which abstinence was indisputable, the sign has never been present. It cannot be yet absolutely affirmed that the sign is specific of alcoholism. At present it is difficult to elucidate its pathogeny. If its specific value can be demonstrated, it will afford a very useful means of diagnosis. It is not yet known to the public, and is easily applied.—*Archives de Neurologie, Number* 66, June, 1901.

Case of Dermoid Cyst with Oily Contents at the Internal Angle of the Orbit.—Chavasse reports the observation of an orbital dermoid cyst, interesting for the following peculiarities. 1. The cyst adhered by a fibrous pedicle to the suture of junction of the frontal bone, with the lachrymal and with the ethmoid. 2. The wall of the cyst had a complete skin covering with well-formed sebaceous glands. 3. The contents were an almost pure oil, composed of fifty-six per cent. of palmitin and forty-four per cent. of olein.—*Le Bulletin Médical*, June 5, 1901.

Treatment by Rest in Bed in Mental Therapy.—Alexandre, Paris, states that in insane asylums the surgical service is less extensive, the more general is the treatment of rest in bed. Metorrhagia, wounds and fractures are far more rare than formerly in this service. There were before this treatment was common, constantly arising, cases of hernia, which had to be reduced, resulting from the various exertions of these patients. Every year there were several operations for strangulated hernia. The reducible hernia is now very rare, and the strangulated hernia absolutely exceptional.—*Archives de Neurologie*, May, 1901.

Delirium in Senile Gangrene.—Paul Fabre reports two cases of this kind. In one, the delirium was melancholic, in the other it was acute with hallucinations of sight and hearing. The delirium did not persist in either case, neither patient being alcoholic. The writer believes that the delirium varies as to its cause in various cases. It may arise from cerebral circulatory disturbances, due to arterio-sclerosis; it may be due to disorders of a septicæmic nature, or it may arise from nervous exhaustion caused by the pain.—*Journal des Praticiens*, June 8, 1901.

The Diazo Reaction of Ehrlich in Diphtheria—Lobligeois states that the diazo reaction of Ehrlich is negative in the urine of diphtheria patients. It is, on the contrary, frequent in scarlatina. This reaction can serve as a diagnostic point in the differentiation between scarlatina and post-errotherapic eruptions.—*La Presse Médicale*, June 12, 1901.

Influence of Theobromine on Work.—Féré shows that one gramme of theobromine taken by mouth, immediately augments muscular contraction. In this way, one obtains thirty-one kilograms in place of twenty-three, but soon the force diminishes, till after some time it becomes decidedly lower than normal.—*La Médecine Moderne*, June 12, 1901.

Upsala Läkareförenings Förhandlingar, No. 8, 1901.

A Case of Cystadenoma Papilliferum of the Accessory Thyroid Gland.—A. Pettersson's patient was a man aged fifty-three years, who for a year had been suffering from a growth in the neck which began as a simple nodule on one side. At the time of operation numerous tumors of varying sizes were found on both sides, extending from the mastoid processes to below the clavicles. These were removed without difficulty. They consisted of connecting strands following the course of the cervical vessels. The subsequent histological examination showed that the nodules were composed mainly of cysts filled partly with colloid material and partly with cauliflower-like papillary masses. The cysts and papillæ were covered with low columnar epithelium, and there were also present islands and strings of epithelium such as are supposed by Wolfler to form the starting point of thyroid adenomata. Cystic tumors of the neck may originate from the branchial clefts, the submaxillary gland, or the thryoid and its accessory glands. The first two possibilities are excluded by the author, who classes his case with the rare papillary cystadenomata of the accessory thyroids. The prognosis in such cases is always colored by the fact that particularly in the thryoid do we find tumors which histologically are typical adenomata and yet infiltrate and form metastases and papillary cystadenomata are especially to be suspected.

Foreign Body in the Trachea Removed by Tracheotomy.—P. Haglund performed a low tracheotomy on a boy aged two and three-quarter years, who three and one-half hours before coming into the hospital had swallowed a pea. The initial attack of dyspnœa had already been recovered from and the patient was suffering no discomfort, but the operation seemed indicated, as palpation of the trachea and larynx gave an impression as if a foreign body were moving within. Two days later, upon reintroducing the tube, which had been temporarily removed, the pea was expelled unaltered, and rapid recovery followed. In discussing the case, the author emphasized the euphoria which is characteristic for foreign bodies in the trachea, and advocated early tracheotomy not only in cases with a positive diagnosis, but also when the presence of the foreign body in the trachea can only be suspected. The incision should be free, and it is better to desist from attempts at extraction, for when the opening is ample spontaneous expulsion usually takes place.

A Case of So-called Stokes-Adams Disease.—R. Friberger's patient, a man aged seventy-six years, had always

been exceptionally healthy until about two years ago, when he suddenly had a series of attacks of unconsciousness, not followed by any paralysis, which were frequently repeated during a period of several days. Such periods of seizure have been repeated from time to time up to the present date. Between the attacks the patient had no dyspnœa, examination of the urine was negative, there was no elevation of temperature. The heart, so far as examination was possible, owing to marked emphysema, seemed normal except for irregularity in force and rhythm. There was no paralysis or disturbance of sensation; the reflexes were all normal. A few moments before an attack the pulse disappeared completely, the face grew pale, respiration became deep and stertorous, and consciousness was lost; the urine was passed involuntarily, and there were slow contortions of the body and extremities. The period of pulselessness lasted about ten seconds, after which there were several strong heart-beats, the face flushed deeply, and consciousness returned. The attacks were gradually decreased and finally checked entirely by the use of stimulants, and nitroglycerin, which latter appeared especially efficacious. Authorities differ as to the causation of the phenomenon. Stokes ascribed it to fatty heart; Charcot and Huchard say that the medulla is at fault, while others, like Dehio, think the heart itself is the seat of the trouble. The symptom complex also appears in other conditions besides arteriosclerosis, *e. g.*, compression of the cervical cord, uræmia, intoxications, etc.

The Journal of Tropical Medicine, June 15, 1901.

Notes on a Case of Amok.—John E. Gimlette describes the physical condition known in English as "running amuck," which is a fairly common occurrence among the Malays. It is characterized by: (1) A sudden paroxysmal homicide in the male, with evident loss of self-control; (2) a prodranal period of mental depression; (3) a fixed idea to persist in reckless homicide without any motive; (4) a subsequent loss of memory for the acts committed at the time. The Malays do not regard the occurrence as an exhibition of true insanity, being more inclined to ascribe it to a spiritual agency, and throughout the East the tendency is to regard it as a vice or crime rather than a disease. The author thinks that the mental upheaval of amok has some of the clinical features of epileptic mania.

An Easy Method of Mounting Mosquitos.—J. Cropper says that all that is necessary is a number of pieces of the brown cardboard of which boxes are made, of the size of a microscope slide, punched with a gun-wad punch five-eighths in diameter. These can easily be fixed to slides with glue or Canada balsam. A second glass slide, fixed to the other side of the cardboard slip, makes the whole complete. The mosquito can be fixed to the glass by a minute drop of balsam or by the tips of the wings, and in this way is readily available for inspection. A little creosote brushed over the edge of the cardboard slip will prevent mold. Entomologists will, of course, prefer pinned specimens.

The Prevalence of Pinta on the Gold Coast.—Osborne Browne says that on the Gold Coast this disease is very common. At first it begins as a very itchy, dark-bluish or black spot, usually on the back of the hand or dorsum of the foot, although it not rarely extends to the palms or soles. At a later stage the initial dark color is succeeded by a grayish pink or white, denoting a loss of the natural pigment of the skin. The fungus is in all cases identical.

The Persistency of Plague.—An editorial calls attention to the fact that Hong Kong is now passing through a severe recrudescence of plague, the seventh definite outbreak within eight years. Over a thousand deaths are already reported this year, and the disease is only just attaining the maximum of its fatality. Racial immunity and racial incidence seem to play no part in the onset of plague; household and personal cleanliness would seem to have little to do with the spread of the disease; nor can public sanitation claim that it has done much to thwart plague in its virulence or in its spread.

Mosquitos Collected in Hong-Kong During the First Quarter of 1901.—J. C. Thomson reports that some 7,400 mosquitos have been received and examined, and the proportion of Anopheles to Culex mosquitos proved to be as 1:27 to 7,263. For the three months the numbers of Anopheles were for January 143, February 35, and March 49. These numbers coincide in their rise and fall with the prevalence of malaria in the colony, for during either February or March in most years the cases of malaria reach their minimum. Mosquitos should be caught by means of glass test tubes and killed by a few whiffs of smoke. No packing of any kind is necessary other than the wrapping of the box in a piece of paper. Mosquitos should be examined within twenty-four hours after capture.

Health Conditions in Trinidad.—The Annual Report by Sir Francis Lovell says that Taus has been greatly benefited by the thyroid treatment. Dysentery has been less prevalent than in former years. Whooping cough prevailed as a mild epidemic. Pani Ghao is prevalent during the rainy season. Twelve hundred and thirty-six cases of malaria were reported, 854 being Tertian. Out of a total of 23,403 cases of all disease treated, *one* case only of typhoid was met with, but under the reports of the medical districts several cases are mentioned.

Norsk Magazin for Lægevidenskaben. June 1901.

Necrosis and Hemorrhage of the Pancreas and Multiple Fatty Necroses.—Francis Harbitz reports three cases. He holds that pre-existing obesity plays a large part in the etiology. "Hemorrhagic pancreatitis" he considers to be a misnomer, inasmuch as there is no primary inflammation of either pancreas or adipose tissue, but rather primary necroses, giving rise to inflammation and hæmorrhage. He does not consider the disease due to an infective process, as no microbes have been found either by means of microscopic examinations or cultures. Death results, not from hæmorrhage, nor from pressure on the sympathetic ganglia and nervous plexuses, but from total or nearly total destruction of the substance of the pancreas.

Hemorrhages of the Skin and Mucous Membrane in a Hysterical Patient—Death from Apoplexy of the Pancreas.—S. Holth describes the case of a young woman who for eight years was subject to cutaneous hemorrhagic spots following any psychic emotion. Hemorrhagic bullæ also appeared on the mucous membranes. Hydrotherapy did not permanently improve her condition. Arsenic was administered for two years, in 12 mg. doses daily of arsenious acid, and seemed to be of great benefit. Death occurred very suddenly. At the autopsy an enormous amount of omental and retroperitoneal fat was found, with about two litres of blood in the peritoneal cavity, which came from a source near the "cauda pancreatis." The author believes that the accumulation of fat was perhaps due to the prolonged arsenic treatment, and that the hemorrhage of the pancreas may perhaps have been of hysterical origin. The patient never had hæmophilic, in the ordinary sense of the word, for in the extraction of teeth, and in an operation for a tuberculous affection of the foot, the loss of blood was insignificant. She was not anæmic, nor did her urine show any trace of albumin or sugar.

The Treatment of Pulmonary Tuberculosis.—C. F. Larsen believes that the diet of tuberculous patients should not consist of "stuffing," but should be sufficient to nourish, and at times to repair the waste caused by fever and inanition. He does not approve of forcing albuminous and fatty foods.

Finska Läkaresällskapets Handlingar, May, 1901.

The Causes of Retraction of the Anterior Chamber of the Eye in Primary Glaucoma.—V. Grönholm, as a result of experimentation, concludes that it is not possible to explain the two constant symptoms of glaucoma—retraction of the anterior chamber and hyperæmia of the ciliary body of the theories of retention or of hypersecretion of Von Graefe, Donders and others. The author holds that glaucoma develops by reason of a dilatation of the blood vessels of the ciliary body; this dilatation causes a hypersecretion and a pressure which push the attachments of the iris forward and cause retention of the aqueous humors.

Embolus in the Superior Mesenteric Artery.—R. Sievers reports the case of a woman suffering from anæurism of the aorta, who was suddenly taken ill and died in twenty-nine hours. An embolus six cms. long was found in the superior mesenteric artery. The author agrees with Litten in considering the mesenteric artery functionally a terminal artery, although not so anatomically. Embolus of this artery, with symptoms of occlusia, is not rare.

Revue de Chirurgie, June 10, 1901.

The Coincidence of Symmetrical Lipomata, with General Progressive Paralysis.—Charles Feré and Marthe Francillon describes several cases. The theories in regard to multiple lipoma have been many, but fail to account for the symmetry of such tumors as the ones described by the authors. They conclude that symmetrical lipomata found in conjunction with general paralysis, which developed before the nervous trouble, should not be considered as trophic disturbances due to lesions of the nervous system, but as teratomata, or embryomata.

Blood Examinations in Surgery.—Jaques Silhol urges that the blood be examined in surgical cases, with a special view to diagnosis. The amount of hæmoglobia should be estimated, and the red and white corpuscles, and dry preparations made in order to ascertain the varieties of leucocytes—and the changes in shape of the blood cells. By these means we can ascertain the state of the blood, which will indicate the gravity of the affection, and the powers of resistance of the patient. When the hæmoglobia is less than forty per cent, for instance, Mickulicz will not operate. Certain blood conditions assist in diagnosis, as for instanee by indicating neoplasms of the stomach, when taken in conjunction with gastric symptoms or by pointing to appendicitis.

Archives Générales de Médecine, June, 1901.

Treatment of Aneurism by Subcutaneous Injections of Gelatin.—Henri Grenet and G. Piquand hold that this treatment may be useful in the fusiform, as well as in the sacculated aneurism, but the reports in regard to it are so inconclusive that it is not possible to make a positive assertion as to its value. The pain and the fever following the injections are due to the action of the gelatin. It has not yet been absolutely demonstrated that emboli and large coagulations are found. If the gelatin enters the blood unchanged, it might readily determine a harmful increase of pressure within large aneurisms with weakened walls. Further study and researches are needed on the subject.

Intra-Pericardial Rupture of the Aorta.—V. Chappet and Louis Gallavardin report a case which they analyze in detail. As a cause of rupture we must take into consideration the possibility of an inflammatory nodule in the external coat of the aorta, obliterating the blood vessels and causing the necrosis of the subjacent portions of the media and interna. Rupture, as a rule, follows secondary lesions, consisting usually of the irruption of blood between the coats of the aorta, either by direct perforation of the wall, by perforation preceded by the dissection of an internal flap, by the formation of a dissecting aneurism lowed by rupture, or by a false aneurism.

Linear Dermatoses.—J. Balzer and L. Alquier give this name to eruptions arranged in long lines not over one or two centimetres in breadth. In contradistinction to dermatoses, arranged in bands, they cannot be said to correspond to any special nerve area. They may have the appearance of acquired cutaneous affections, such as eczema, psoriasis, lichen; of congenital affections, such as nœvi, ichthyosis, or of his well-defined cutaneous troubles The authors describe thirty-two cases. As yet, the reason for the linear arrangement is unknown. Many authorities lean to the embryonal theory, but even were that adopted, it would not be clear whether the defect in development simply creates a linear locus minoris resistentivé on which various skin affections find a suitable location for evolution or whether it causes the dermatoses themselves.

OUR LONDON LETTER.

(From Our Special Correspondent.)

WAR MEDALS—REORGANIZATION OF THE BRITISH MEDICAL ASSOCIATION—LONDON UNIVERSITY—VICTORIA UNIVERSITY—THE MEDICAL COUNCIL AND THE COLLEGES—DR. IRWINE'S CASE.

LONDON, June 14, 1901.

WEDNESDAY was a red-letter day for the volunteers who have returned from the war, for with great ceremony the King presented medals to about 3,000 of them with some 200 officers of the army and navy, beginning with Lord Roberts. The surgeons included Sir William MacCormac, Sir F. Treves, and Sir W. Thomson. The pageant was one of the most brilliant that could be devised. The aged Duke of Cambridge was present, though he is now rather feeble, and was evidently much interested. The Princess Victoria was specially attentive to her aged relative and persuaded him to take a seat before the ceremony was concluded. You will remember H. R. H. is now 82.

The approaching annual meeting of the British Medical Association is more than usually important on account of the proposed reorganization. The report of the committee on the subject has now been before the branches for several months and has been discussed by many with varying results. On the whole, it may be said that the branches seem to be in favor of, or at least favorably disposed towards, the changes suggested by the committee. On the other hand, there has been evinced no little opposition, and much destructive criticisim has been pronounced. The supporters of the committee hold that the changes proposed would tend to make the Association co-extensive with the profession, in fact, they seem to suppose nearly every regular practitioner would enroll himself as a member. The opposition think this a vain aspiration and even question whether such a result is desirable. Then there is the dead weight of indifference and even of satisfaction with what has been achieved to be reckoned with, and most of all perhaps distrust, of the Council or its more active set. With all its faults the Association has prospered under the old constitution, and moderate reforms, it is argued, rather than radical changes would suffice to bring it into touch with the profession of to-day. It must not be forgotten, too, that since it has been made a limited company the rules of such bodies must be regarded and are perhaps sufficient to do all that is desirable. The meeting at Cheltenham thus has much to consider.

The London University has undergone the process of reorganization, but at present the result is not very tempting to impatient reformers. At present its new constitution is scarcely at work and there is much chafing at the continual delays. The *Times* is publishing a series of articles on the organization of university education in London, in which the need of large sums of money is urged, but whether these will be forthcoming is very doubtful. The fact is, the University as reorganized no more accords with the general idea of such a body than it did before the change. Then it was a mere examining board. Now it is rather a federation of colleges and schools of all kinds with the old examining institutions. Naturally there is much fear lest the old exaltation of examinations should still prevail, and misgiving as to whether the interests of the various included institutions can be reconciled.

An object lesson as to this danger is just now to be seen in the case of the Victoria University. The Liverpool College is no longer contented with its position and wants to become a full-fledged university itself. Liverpool is rich and generous as well as ambitious. Her merchant princes would no doubt endow a university established in their city. They have shown their mettle in establishing a School of Tropical Medicine. But if the Liverpool College obtained a charter Manchester, the seat of Owen's College, the centre of the Victoria University, would demand an equal position. Owens was indeed the origin of the Victoria, and when it wanted a charter its request was granted, but Liverpool and Leeds Colleges were joined with it. Whether this union shall be dissolved is now a burning question with both Manchester and Liverpool, and local feelings seem to be receiving more attention than the greater question as to what would be best for the advancement of higher education in both cities. Leeds does not seem to receive much consideration from either of her big sisters.

On Saturday the case of Dr. Irwine was brought to a conclusion. There was a full meeting of the Council, and some persons seemed to be rather anxious as to whether Dr. Irwine would turn up or further absent himself. He duly appeared, however, in obedience to the order of the Council and stated that as soon as he received the decision of that body he took steps to sever his connection with the Birmingham Institute. He explained the delay that occurred before completing that severance by the terms of his agreement with the Institute and said he had acted all along under the advice of the London and Counties Medical Protective Society. The secretary of that body, Dr. Woods, read the correspondence between the Society and Dr. Irwine. Then Dr. Bateman, of the Defence Union, put in two pamphlets with Dr. Irwine's name on them, and said further that name still appears on a plate at the Institute. Dr. Irwine said he had only heard that morning of this and had telegraphed to have the plate removed. In reply to questions he said he had handed in his resignation on February 21, that he quite understood that the Council's objection was to the advertisements—that the fee was not the question, but the solicitation by advertising of persons to avail themselves of the reduced fee. The Council then deliberated *in camera* after which the president informed Dr. Irwine that it was decided to proceed no further. So the case fizzled out and a good many people think it would have been as well if it had not been taken up, for the Council has lost rather than gained in prestige and has suffered a slight at the hands of the Privy Council. But perhaps the government ought to be made to feel the danger of insulting the whole profession, as the vice-president and Colonial Secretary did in Parliament, for the sake of supporting the pet scheme of the latter's brother.

The Council then proceeded to discuss its dispute with the two London colleges anent their notices that they will no longer require candidates for their diplomas to produce the Council's certificates of registration as students. I have apprised you of the steps leading up to

this defiance of the council by the Colleges in their attempt to steal a march on the other licensing bodies. It is hardly to be expected that the other corporations will maintain regulations which these two repudiate

Dr. N. Moore supported the colleges in a lengthy speech, declaring that they were as desirous as the Council of improving education in science. But the reason of the differences that had arisen was the want of confidence of the Council in the ability of the Colleges to decide where the scientific instruction should be given. The Colleges had laid down explicit rules to ensure that the institutions they recognized possessed adequate means of instruction in science. A preliminary examination must be passed and the age of 16 reached before the scientific instruction could be begun, so that it was not right to assert that the profession would be flooded with immature students. He held that the Council could not well undertake the supervision and visitation of the places where science was taught and would do better to leave the matter to the colleges. They had undoubted rights which they declined to sacrifice even to preserve registration, which they valued. They were open to consider criticism by the Council of any special case and would examine such case with the greatest care and respect for the opinion of the Council. They would even furnish a list for such critisism—but not for recognition.

NEPHRORRHAPHY WITH FLAP FIXATION.

To the Editor of the Medical Record:

Sir: If surgeons who are interested in the subject of nephrorrhaphy with fixation by the use of capsular flaps, including Dr. Arnold Sturmdorf, who has an interesting contribution on this subject in your issue of June 22d, will turn to the *Journal of the American Medical Association*, of January 28th, 1899, page 177, they will find this measure fully described in almost every detail as given by Dr. Sturmdorf. At the time that I published this description my first patient had been operated on less than one year (January 20th, 1898). I presume I have made thirty operations by this method, and thus far without a single failure. It is unnecessary to anchor the kidney with stay sutures of any kind Drainage is unnecessary.

In my description, I suggested, as does Dr. Sturmdorf, the making of two columns of muscular tissue so that each column could be attached to a flap of the capsule This is unnecessary, since a single column answers every purpose, a flap of capsule being brought up on each side of this column, and the flaps attached by sutures so introduced as to embrace the column of tissue, the flaps on each side, and the adjacent tissue on the outside of each flap. Three or four of these sutures will be sufficient. The overlying tissue is then brought together either with catgut in layers or by through-and-through silk-worm-gut sutures, as the thickness of tissue or the judgment of the operator may suggest.

It is, of course, pleasant to have this method adopted by such surgeons as Morris and Sturmdorf. As to the matter of originality, that is of comparatively little importance. At the time that I published this method in the Association *Journal*, I had never heard of the method as being used by any one before me, and from the correspondence with several eminent surgeons, which followed the publication of this report, I was led to infer that the method was original with me. The method itself, however, seems so simple that it would be surprising if others had not previously used it.

J. F. Baldwin, M D

Columbus O., June 24, 1901.

A Contribution to the Diseases of the Bronchial Lymph Glands.—F. Schlagenhaufer reports three cases which throw an interesting light on the origin of many cases of cryptogenetic pyæmia and so-called idiopathic brain abscess. All three patients were under the age of 21 and died of sudden acute illness with very high temperature and the general manifestations of purulent meningitis. On an autopsy in each case there was found a suppurating bronchial lymph gland, situated below the bifurcation of the trachea close to the right primary bronchus, and surrounded by an area of necrotic tissue, while in addition to various pyæmic foci in other organs there were numerous metastatic abscesses in the brain. In all these instances there was evidence of tuberculosis, though in one case the lung had not yet been invaded.—*Wiener Klinische Wochenschrift*, June 6, 1901.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION OF MEDICINE.

Stated Meeting, held May 21, 1901

E. Franklin Smith, M. D., Chairman.

The Etiology of Acute Articular Rheumatism.—Dr. Nathan E. Brill said that much attention had recently been directed to the etiology of acute articular rheumatism, and the case he presented had some bearing upon that aspect of the subject. The patient was a man who was admitted to his service at Mt. Sinai Hospital on February 5th of the present year. His family history was negative and there was no history of syphilis. His present illness was of four weeks' duration, and began with pains in both legs, but no swelling or redness. He had an eruption on the body which had existed for several weeks His temperature at the time of his admission was 100° and went up to 103° that afternoon. He shortly afterwards developed signs of a pleurisy on the right side. There was tenderness over both tibiæ, and he complained of pain in the left sterno-clavicular articulation and in the fingers of the left hand. Three or four days after his admission the erythematous eruption over his body became much more profuse; some of the papules became larger, approaching in appearance a typical erythema nodosum. Examination of the blood showed a leucocytosis ranging from 10,000 to 19,000. During the past two weeks the man had been absolutely free from fever, but the disease had left him with partial ankylosis of the fingers of the left hand. Blood cultures were made upon five occasions by Dr. Libman and in one instance a streptococcus was found. The man's temperature had been of a very intermittent form, sometimes ranging from 100° to 105° in the course of a day. He was given one dose of antistreptococcus serum, and from that time on his symptoms began to abate.

Dr. E. Libman, who made the blood cultures in the case shown by Dr. Brill, said it was difficult to say whether the streptococcus he found was identical with that which has been described by Wassermann. Five cultures were made upon a medium similar to that employed by Wassermann, and the second culture, made on February 10th, gave two colonies of streptococci; the first culture, as well as the last three, gave no results. The streptococci obtained were injected into three rabbits, and three days later the animals limped and the joints were apparently tender, but there was no swelling. The rabbits were subsequently killed In two of them no effects of the inoculations were found, while in the third one vegetations were present on the chordæ tendineæ. There were no joint affections The inoculations apparently produced no effect on guinea pigs

A Case of Human Myasis and Cantharias Tenebrioobscurus, with Demonstration of Larva and Drawings.—Dr. J. J. Walsh said that two months ago he was consulted by a woman who brought with her a worm which she said she had passed from the anus. He recognized it as the larva of one of the beetles and sent it to the Entomological Department at Washington for further information. They reported that it was a species of meal-worm which has occasionally been found in human beings. The worm lays its eggs in meal, and is rather common in this country.

Dr Walsh said his patient had been using rectal suppositories made of gluten, which is practically a meal product and is formed without sufficient heat to destroy germs that may exist in the meal originally.

Colloid Cancer of the Stomach and Omentum.—Dr. Stephen Smith Burt read a paper on this subject and

reported the following case which had recently occurred in his service at the New York Post-Graduate Hospital: M. P., male, aged 43 years, married, a native of Bohemia, and by occupation a laborer. His family history was good. The only important point in his previous history was that he had syphilis seven years ago.

In May, 1900, he had an attack of pain in the right hypochondriac region and subsequently in other parts of the abdomen, which lasted about three months. Eight weeks ago he noticed for the first time that his abdomen was enlarged and four weeks later that his feet were swollen, especially towards evening. He had been constipated for two months. He complained chiefly of distress in the abdomen, general debility, and constipation. Repeated examinations of the urine revealed nothing of much importance, excepting a high specific gravity associated with a small daily excretion. The patient was very pale and cachectic and extremely emaciated; there was no jaundice; the abdomen was symmetrically enlarged; the superficial abdominal veins were not prominent; there was nothing abnormal about the umbilicus; the feet and ankles were œdematous. The abdominal parietes were tense and resistant and there was ill-defined fluctuation. In the left upper quadrant of the abdomen there were a number of more or less plainly appreciable, irregular, hard, nodular masses. Upon a subsequent examination, following the withdrawal of 190 ounces of fluid from the abdominal cavity, these nodular tumors could be detected extending into the lower half of the abdomen. The inguinal glands were moderately enlarged. Dilatation of the stomach was not manifest. The resonance varied between flatness at the lower part of the abdomen and dulness at the upper portion. There was never any vomiting and the contents of the stomach were not analysed. The temperature was either normal or sub-normal, and remained so until the day before death, when it rose to 103° F. The pulse was generally small and weak, but never rapid. The daily quantity of urine excreted was about twenty ounces. Anæmia was present and progressive; there was no jaundice, hemorrhage, or vomiting, and the mind remained clear until the patient was nearly moribund. The patient usually slept well at night and was able to be up and about the ward and frequently out of doors. He complained of more or less discomfort or actual pain, usually in the region of the epigastrium, but for the relief of this he did not require an opiate until the day before his death, which occurred on February 6, 1901, chiefly from asthenia.

The diagnosis made in this case was colloid carcinoma of the stomach and omentum, the left lobe of the liver, and the transverse colon. The true nature of the growth was discovered by a rather rare and fortuitous circumstance. During the man's illness it was frequently necessary to tap the abdominal cavity in order to relieve the distress caused by the rapid accumulation of the fluid, and upon two or three occasions fragments of the growth escaped through the cannula. These specimens were sent to the laboratory and were pronounced by the pathologist, Dr. Henry T. Brooks, to be colloid carcinoma. The autopsy revealed a diffuse colloid carcinoma of the stomach, omentum, mesentery and peritoneum, and of the left costal, diaphragmatic, and pulmonary pleuræ.

Dr. Beverley Robinson said that so far as he could recollect he had never seen a case of colloid cancer of the stomach, and only two or three of colloid cancer of the omentum or peritoneum. Last fall a patient died at St. Luke's Hospital and the autopsy showed that the case was one of colloid cancer, involving principally the peritoneum. During life the case had been looked upon as one of tuberculous peritonitis, and even an exploratory incision failed to reveal the true diagnosis. There was little or no fever and the emaciation was not very rapid. The fluid which was withdrawn from the abdominal cavity was ascitic in character and could not be differentiated from that of tuberculous peritonitis. These cases were very rare and the diagnosis was difficult. Dr. Burt was fortunate in having secured shreds of the cancerous tissue for microscopical examination.

Dr. Thomas E. Satterthwaite said that colloid cancer of the stomach was so rare an affection that few had the opportunity of seeing a case. Colloid cancer itself was very rare in comparison with other varieties of malignant disease. The speaker said Dr. Burt's case was the only one he could recall in which the diagnosis had been made during life. The value of an exploratory incision in the recognition of doubtful cases of this character should not be lost sight of.

Dr. Satterthwaite said that although the tubercles of colloid cancer could be very large they might also be very minute, and readily be mistaken for tuberculosis, even under the microscope, by one who was not an expert pathologist. The usual bulky form of the tumor might prove of assistance in making the diagnosis.

Dr. Max Einhorn said his experience with this form of cancer was very limited and he knew of no other case in which the diagnosis was made during life. Some years ago he saw a case of colloid cancer involving the posterior wall of the stomach. This patient's chief complaint was pain in the region of the stomach. There was no vomiting, nor constipation, and the loss of flesh was not great. Nothing could be detected by palpation and an examination of the stomach contents proved negative. The motor function of the stomach was apparently disturbed, and as nothing could be done for the man in a medical way it was decided to operate. The operation revealed the true nature of the trouble. The man died a few days later, and under the microscope the growth on the posterior wall of the stomach was found to be a colloid cancer. The pylorus was not involved by the growth.

Dr. Andrew H. Smith said he has had a case of suspected colloid cancer under his observation since last December. The patient was man seventy-four years old, with a certain amount of anasarca, some degree of fullness of the abdomen and some enlargement of the liver. There was a soft cardiac murmur and the action of the heart was exceedingly irregular. The urine had a low specific gravity; it contained no albumin and only an occasional cast. The case was first regarded as one of cardiac insufficiency, with possibly a certain amount of disease of the liver. The abdomen gradually became more distended, but palpation did not give the sensation usually communicated by fluid, and a change in the position of the patient produced very little change in the level of the abdominal contents. Two attempts were subsequently made to draw off fluid with the trocar, but in each instance only a small quantity was obtained, and the instrument apparently came in contact with something that interfered with the flow of the fluid. For a time the kidneys almost ceased to excrete any urine and the anasarca became so pronounced that it had to be relieved by very free catharsis. After a period of inaction, during which only about fifteen ounces of urine were secreted daily, the kidneys, in the course of twenty-four hours again became active, secreting from fifty to sixty ounces of urine daily. Dr. Smith said he was inclined to attribute this temporary disturbance of the function of the kidney to the pressure of a rapidly growing mass and that the relief of the pressure was due to the fact that the mechanical relation of the mass to the renal vessels, had suddenly changed, and again permitted the free flow of urine through those vessels. This patient was now in a very deplorable condition and probably will not live much longer. Against the diagnosis of colloid cancer in this case was the absence of anything like a nodular condition. The patient had never suffered from pain or vomiting, but the latter symptom is usually absent when both gastric orifices are free.

Dr. Burt, in closing, said he knew of but two other

cases of colloid cancer—both of the omentum—in which the diagnosis was made during life. He did not know of a single case in which the diagnosis of colloid cancer of the stomach was made during life. In both of the two cases referred to the diagnosis was made with the aid of an exploratory incision, colloid cancer not having been previously suspected. In his own case, Dr. Burt said he was satisfied that he had to deal with a cancer, but he did not know that it was of the colloid variety until some of the material had escaped through the needle.

Some Points of Intracranial Neoplasm considered from the Neuronic Standpoint.—By F. Savary Pearce M. D., of Philadelphia. In this paper, the author dwelt upon the theory of movement of the ultimate nerve element, the neuron; and through this separation of dendrites and collaterals the regulation or not of nerve impulses which have been generated (*endogenous*) or modified by the brain mass, where the energy here has been due to *exogenous* causes.

The point was made that many symptoms of brain, tumor, such as the hysterical, paræsthetic, anæsthetic paralyses or convulsions, not localizable by the known scientific anatomico-physiological facts were at all times difficult (*never* consistent in hysterical phenomena) or impossible to correlate with the well-known anatomical division into ganglia and tracts. As it is normally the inhibitions of cerebral and spinal activities control impulses in a regular fashion. When tumors produce insidious irritation of the protoplasmic mass of nerve cells, it is reasonable to suppose such irritation may cause retraction of the processes, or by disturbance of circulation cause intercellular pressure, which may also be a cause for breach of contact of certain ganglia, as the basal, and tracts.

It will be thus seen in logical sequence if impulses (nerve energy, or, as some observers have conceived, the possibility of this force as being a form of electricity working in the highest possible mechanism) are changed in their transmission from the definite and normal channels through the ganglia and various tracts.

Theoretically the said nerve impulses could be diverted in various and irregular directions to the disturbance of *all* known classic symptomatology of intracranial neoplasm. In such widespread disturbance depending upon the idiosyncracy of the nerve protoplasm, will aberrant symptoms prevail. So that, accurate as we may be in anatomy and physiology, the irregular control of nerve impulse in this manner in brain tumor would set aside the said mechanical relations of function with the central nervous system, leaving an irregular array of phenomena indicated above and which must be taken into account in the study of this most difficult branch of medicine.

Complex bodlly movements etc., we frequently know *why* are perverted, but we are only dimly conscious of *how* they are produced, hence the justification of this interesting speculation of a theory which may presage a fact.

Dr. Charles L. Dana said he did not know exactly what Dr. Pearce meant by the "neuronic theory." He probably meant that certain psychical processes are due to the separation of the dendrites of one neuron from those of another. This theory has found some adherants, but it is hardly possible to discuss it, as it is practically unproven and is not supported by a single scientific observation. There is no doubt about the existence of the neuron: it is the biological unit in the nervous system, but this fact will not justify us in drawing inferences by which we can explain physiological phenomena. The hypothesis of Dr. Pearce, namely, that certain symptoms of brain tumor are the result of retraction or separation of the dendrites, while it cannot be either proven or disproven, does not add very much to our knowledge of the situation and nothing at all to our capacity to diagnose brain tumors.

Dr. Dana said that during the past few years, very little progress has been made in the recognition of brain tumors and their localization. In diagnosis of brain tumor, the studies in the pathology of the blood now give us some light: for example, the presence of marked leucocytosis will possibly enable us to decide whether we have to deal with an abscess or a tumor, and it its not unlikely that a further investigation of the "eosinophilia" of the blood may help us in recognizing the kind of tumor. In the localization of cerebral brain tumors, a study of the presence or absence of the motor touch, the sense by which we recognize the form of an object, may prove serviceable. The loss of certain local reflexes may also prove helpful, while the symptoms of acromegaly will lead us to suspect that the pituitary gland is involved. Percussion of the skull has been of value in some instances. Thus far we have received no assistance from the Roentgen rays in the discovery of brain tumors.

Dr. B. Sachs said the idea of associating the neuronic theory with tumor of the brain was like bringing a pigmy and a giant together. One is associated in our minds with something that is gross; the other with something minute. Of course, there must be some connection between them, in a way, because the neuron is the basis of the entire structure of the nervous system but the idea of trying to explain the symptoms of such a gross lesion upon any theory which involves the neuron seems to be rather hazardous. The one practical point in connection with the neuronic theory is that it does away with the distinction formerly made between diseases of the gray and of the white matter, and enables us to understand that apparently both of these structures may be simultaneously affected.

Aside from mere speculation, Dr. Sachs said, we have a knowledge of certain points in connection with the localization of brain tumors. We know that if a growth is located in a certain area, it will give rise to "signal" symptoms, while if it is located in what have been termed the "silent" parts of the brain, it does not present any symptoms. The percentage of cases of tumor of the brain in which we are not able to make the diagnosis is not great.

Dr. Pearce, in closing, said that while the theory he had suggested in his paper was not proven, and no statistics could be offered to support it, still, it could not be disproven. Briefly stated, the theory is that a growing tumor in the brain is able to excite certain activities of the adjacents cells, or, by pressure, produce separation of the neurons or interfere with their circulation, which in turn produces an aberration of the function of those cells, and the impulse is not distributedtin the proper direction, as it would be in health.

Splenic Myelogenous Leukæmia, with Pulmonary, Laryngeal and Faucial Tuberculosis.—Dr. Arnold Sturmdorf reported this case. The patient was a woman, thirty-five years old, married, and the mother of a healthy child, now two years old. The family history is negative, with the exception that one sister died of tuberculosis, while a second is said to have recovered from the disease. The patient was born in Brooklyn. From her second to her tenth year she lived in the northern part of Ireland, after which she returned to Brooklyn, where she has since resided.

Splenic enlargement was first noticed incidently during her normal puerperal convalescence two years ago. As it caused no inconvenience, it was ignored. Her present illness began on New Year's day, 1901, when, without premonitory symptoms or apparent cause, she awoke suffering from pain in the throat, cough and hoarseness. After several weeks of unsuccessful treatment, her physician sent her to Lakewood, where

she remained five weeks without apparent benefit. From that time to the present she had gradually grown worse, and has lost about twelve pounds in weight.

Examination, April 17, 1901:—Spleen, enormously enlarged, hard, smooth, and prolapsed; not painful. Its upper pole can be palpated for a short distance beneath the left costal arch; its anterior border, sharply demarcated, extends over into the right side several fingers' breadth beyond the middle line, and presents a distinct indentation at the level of the umbilicus. Its lower pole dips deep into the pelvis, where its characteristic edge can be palpated through the anterior vaginal wall, between the bladder and uterus, the latter being crowded backward.

The lungs present indistinct cavernous signs between the clavicle and third rib on the right side anteriorly and over the left supra-scapular space posteriorly. The uvula and left half of the faucial arch, including the pillars and tonsil, are diffusely red and infiltrated. The junction of the left uvular border and soft palate is deeply fissured. This whole involved area presents a number of discrete, small, round, superficial ulcers covered by a grayish-yellow coating. The tonsillar crypts are filled with yellow semi-solid plugs. The epiglottis is pale, but otherwise normal. The glottis is obscured by a characteristic pyriform swelling of the left arytenoid, and numerous papillomatous excrescences filling the inter-aryteniod space. Sputum, and smears from the faucial ulcerations show tubercle bacilli in abundance.

Many blood counts were made. These showed characteristic fluctuations, which may be summarized as follows:—(1) The occurrence of febrile temperature is accompanied by a characteristic alteration in the relative proportions, but not in the sum total of the white corpuscles. (2.) This alteration is manifested principally in the polymorphonuclear and myelocyte elements. (3.) The polymorphonuclear count rises parallel with the temperature curve, while the myelocytes decrease proportionately. (4.) The rapid increase in the number of the polymorphonuclear elements suggests an intercurrent leucocytosis.

The first blood count, made on April 17th, gave the following results:—Hæmaglobin, forty-eight per cent.; (Gower). Red corpuscles, 2,800,000; white corpuscles, 156,000; ratio, about 1:18. On May 10th the hæmaglobin was fifty-two per cent.; red corpuscles, 3,200,000; white corpuscles, 116,000.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting held May 20, 1901.

PARKER SYMS, M. D., PRESIDENT.

Cancer of the Posterior Wall of the Larynx Involving the Œsophagus.—DR. FRANCIS J. QUINLAN exhibited this specimen, which had been taken from a woman who had presented herself at the hospital complaining of excessive ptyalism. It was some time before the growth could be mapped out and a portion snared off for microscopical examination. It was eventually found to be an inoperable carcinoma. An attempt was made to treat the case by Dr. Dawbarn's method of ligation of the carotids, but it was found impossible to include all of the important arterial branches in the ligature, and the woman died a short time afterward.

Prostate Removed by Perineal Prostatectomy.—DR. PARKER SYMS presented a prostate that had been removed by him on January 24, 1901, from a man of sixty-two years. The man had suffered from complete retention of urine for a number of months prior to the operation, passing the overflow and requiring frequent catheterization. The prostate had been removed by perineal prostatectomy without a suprapubic incision. This had been accomplished with the aid of a rubber inflatable bulb passed into the bladder through the membranous urethra. It was then inflated to a diameter of about two inches and a half, and by pulling on the rubber stem, which was in reality a rubber drainage tube, the operator was enabled to reach the prostate and enucleate it. The speaker said that he was of the opinion that this method of operaing had greatly reduced the mortality. He had himself operated nine times by this method. All of the patients had lived, and all but one had secured complete restoration of the function of the bladder. In the unsuccessful case the bladder had been so fixed that he had been unable to reach it as he had not at that time devised his special catheter. Microscropical examination had shown that no portion of the bladder or of the urethra was involved in the operation.. These patients were able to retain their urine practically all night, and were cured of their cystitis.

DR. ROBERT NEWMAN said that the case under discussion was certainly one in which nothing else could have been done but an enucleation. He would like to know why Dr. Syms preferred the perineal to the suprapubic incision. It seemed to him that the only objection to the suprapubic incision was that the prostate then lay sodeeply that it could not be easily seen during the operation. This could be overcome by the use of the electric light.

DR. J. W. S. GOULEY said that the operation of prostatectomy had been measurably simplified by the devices employed by Dr. Syms. Ever since enucleation of the prostate had been advocated, he had been opposed to the suprapubic incision, believing it to be a needless complication. The section of the membranous urethra is a simple procedure. On several occasions he had had to reach the prostate for the removal of phosphatic calculi, and had not experienced difficulty in doing this through the perineum. The enucleation of the prostate by the suprapubic incision was very different, and was certainly not advisable.

DR. Syms, in closing, said that he preferred the perineal route because it seemed to him to be the most direct, and the one affording the most direct drainage in the line of gravitation. The bladder in these cases was almost invariably infected, and when the suprapubic incision was made there was always a pocket left from which drainage was incomplete. Dr. Alexander had made use of the suprapubic opening for the purpose of introducing two fingers and forcing the prostate down into the perineal wound. When suprapubic drainage was employed the patient was confined longer in bed. Most of his patients had been out of bed in five or six days, a point of considerable importance to these old men. In his cases the patients had experienced immediate relief, and had shown very slight reaction after the operation. The perineal operation without suprapubic incision was a comparatively slight one, and seemed to him even safer and less formidable than the Bottini operation.

The Vaginal Route Compared with the Abdominal Route in the Surgical Treatment of Pelvic Diseases in Women.—DR. J. RIDDLE GOFFE was the author of this paper. He said that in any disease in the female pelvis which could be treated by the vaginal route with equal safety and success as by the abdominal route, the former should be given the preference because after such operations convalescence is more rapid, there is less fever, and the procedure is safer. At the present time, in his opinion, the only operation indicated for cancer of the uterus was vaginal hysterectomy. The operation, for cancer confined to the uterus itself, was a very simple procedure. According to his experience, simple ovarian cysts and abscesses of the ovary could be removed with perfect success and safety through the vagina. It was a matter of no importance how large that cyst might be, because after it had been tapped and allowed to collapse, it was easy to remove it through the vagina. If the

abscess was large the same method should be adopted. Retroversion of the uterus had been treated by tampons and pessaries, but it was an accepted fact that only about five per cent of those treated by pessaries were cured, the other 95 per cent being compelled to wear a pessary for the remainder of their lives. Retroversion of the uterus could be relieved very simply by an operation through the vagina. It was not a condition which would justify an operation attended by dangers either immediate or remote. A large proportion of the cases in which Alexander's operation was done had infection of the soft tissues; a considerable percentage had either single or double hernia, and the operation was absolutely contraindicated whenever there was any complication, such as disease of the appendages or adhesions. Ventral fixation would certainly cure the retroversion, but it was an operation involving an abdominal section, and this always meant a weakening of the abdominal wall. Because of this tendency to hernia after abdominal section, the speaker had come to look upon every laparotomy as a serious procedure. On the other hand, the peritoneum of the pelvis was much more tolerant of surgical interference than the abdominal peritoneum, and it was well known that this region has a special blood supply. Through a vaginal incision the malposition of the uterus could be rectified and the round ligaments shortened. Most of his vaginal work was done through the anterior fornix, the necessary room for surgical manipulations being secured by combining a longitudinal with a lateral incision. This operation found a specially useful application in young single women. Conservative operations on the appendages could be done with the same facility and thoroughness by the vaginal as by the abdominal route, and so could myomectomy for small fibroid tumors. If the tumor confined to the true pelvis and was not larger than a four-months pregnant uterus, it was perfectly possible to remove it through the vagina. If, however, the fibromatous uterus reached above the true pelvis, it was better to resort to abdominal section.

Dr. William R. Pryor said that far conservative and evacuative procedures the vaginal route far exceeded the abdominal route. He believed that for cancer of the body of the uterus the vaginal operation was an absolute failure. This belief was emphasized by the fact that one observer had reported 1,365 cases of cancer of the uterus operated upon by vaginal hysterectomy, and yet, after three years, it had been possible to trace only 60 women who were alive or who had not had a recurrence of the disease. He thought it was the present consensus of opinion that in cases of gonorrhœal disease of the appendages both appendages should be removed. He had found it possible to relieve by vaginal operation 83 per cent. of the women coming to him with fibroids of the uterus. He believed just as good work could be done through the posterior as through the anterior cul-de-sac, and with somewhat less traumatism, to say nothing of the probability of securing somewhat better drainage through the peritoneal pouch posteriorly. He preferred not to do a myomectomy because fibroids were connected with a diathesis, and the only proper surgical operation was one which would remove them all. Dermoids were ordinarily best removed through the anterior incision. But the great advantage, after all, of the vaginal route was the opportunity it afforded for making exploratory incisions without detriment to the patient, thus providing a valuable means for establishing a correct diagnosis in many doubtful cases.

Dr. A. Brothers said that his experience with the two routes under discussion had been about equal, comprising about 100 operations of each kind. He would insist that it is not so easy to work through the vagina as by the abdominal route, and that the vaginal operation should be attempted only by experts. Surgical operations through the vagina must necessarily be done in a limited space, and in a field more or less obscured by the oozing of blood. The control of hemorrhage was also more difficult per vaginam except for those of large experience in such work. It could not be denied that the reported mortality was much less in vaginal than in abdominal work, though this did not apply to the attempts of tyros in this field. He did not look upon the vaginal route as the one of choice in the majority of cases of suppurative disease in the pelvis. As a general thing, the abdominal route was the one of choice for the surgeon, though the patient ordinarily preferred the other.

Dr. Eden V. Delphey said that the operation of abdominal section, even the mere opening of the abdomen, was attended by far more shock than incision through the vagina. The operation for salpingo-oophoritis was a difficult one if done by the vaginal route, except in the comparatively rare cases in which there were no adhesions.

Dr. Pryor took issue with Dr. Brothers regarding the difficulties of the vaginal operation. He said that the surgeon did not ask for more than three inches of space through which to see the appendages in an abdominal section, and the same amount of space was at his disposal when operating by the vaginal route. There were no important vessels divided in the vaginal operation. It was, however, no longer the abdominal versus the vaginal route, for each operation has its own special field.

Dr. Goffe, in closing, said that in operating through the vagina and working upward it would be found much easier to get into the line of cleavage than when working from above downward.

Penetrating Gunshot Wound of the Abdomen without Injury to the Abdominal Contents.—Dr. Henry Roth read this paper. He said that a number of cases had been reported in which bullets had penetrated the abdomen and had passed among the intestinal coils without doing any serious injury to the bowel. In fifty-eight cases of gunshot wound of the abdomen treated at the Cincinnati Hospital there had been only three in which the viscera had not been perforated. Dr. Roth then reported the following case, which had come under his observation in the hospital service of Dr. Parker Syms: The patient was a boy of ten years who, in July, 1899, had accidentally shot himself with a 22-calibre revolver in the abdomen near the umbilicus. Soon afterward he had begun to vomit, and on the following day he was brought to the hospital. At that time his temperature was 100.6°F., pulse 100 and respirations 22. Under ether, the abdominal wound was explored, and a perforation was found in the peritoneum, but further exploration failed to detect the bullet or any wound of the abdominal contents. The boy recovered, and was about to be discharged from the hospital when attention was directed to a swelling under the skin about six inches to the left of the bullet wound in the umbilical region. This swelling proved to be the bullet, and it was removed. The speaker said it was generally recognized in civil life that when there was a bullet wound of the abdomen an exploration should be made to determine whether or not the peritoneal cavity had been penetrated. Such an exploration should be done as soon as possible and after all preparations had been made for laparotomy. The wound of entrance should be enlarged for a distance of about one inch upward and downward, and then dissected laterally down to the peritoneum. The reports from the Spanish-American war showed that a large number of persons who had gunshot wounds of the abdomen recovered without operation. It must be remembered, however, that a large proportion of those injured in the abdomen died on the field from hemorrhage. Time was a very important element after a battle, hence it was out of the question to spend an hour or more in exploration on a case which was quite possibly hopeless.

Dr. Gouley referred to a dissecting-room subject which had he seen in which a bullet was encysted in the mesentery. There were no signs of injury to the coils of intestine.

Dr. A. Ernest Gallant said that his experience in dispensary work had suggested the necessity for uttering a word of caution against probing needlessly and exploring gunshot wounds. Many cases that had been subjected to such meddlesome surgery had suppurated, whereas such a methed of healing had been decidedly exceptional when an antiseptic dressing had been applied and an expectant plan of treatment adopted.

Dr. Roth, in closing, said that after exposure of the peritoneal surface, in the case just reported by him, there was no doubt that the opening there found had been produced by the bullet, and not by subsequent probing.

Some Incompatibles.—Mineral acids, with alkalies and relatively weak salts of other acids, such as bromides, chlorides, and iodides.

Alkalies, with acids and relatively weak salts.

Arsenic, with tannic acid, salts of iron, lime, and magnesia.

Bitter infusions and tinctures, with salts of iron and lead.

Bromides, with acids, acid salts, or alkalies.

Calomel, with antipyrin, alkalies, lime water, salts of iron and lead, and iodide of potassium.

Spirit of camphor, with water.

Chlorides, with silver salts, lead salts, and alkalies.

Chloroform, with water, except in minute quantity.—*Maryland Medical Journal.*

Various Hints.—Convulsions may be frequently cut short like magic by turning the patient on his left side. The nausea as an after effect of chloroform or ether narcosis may be generally controlled in the same manner.

When chilly from exposure, breathe very deeply and rapidly and the increase in bodily warmth will be surprising.

Vomiting after the administration of chloroform may frequently be prevented by replacing the inhaler with a linen cloth steeped in vinegar, allowing it to remain over the face for some time.

People who have weak hearts should always have their principal meal in the middle of the day, and with as little water as possible.

Many a woman's ruin is due to the old idea that a woman can safely leave her bed on the tenth day after confinement.

Crude petroleum, poured upon a burned surface and covered loosely with cotton, will subdue the pain almost at once.

Black pins in surgical dressings are preferable because they will not rust, and can be more readily seen when they are to be removed.

Strong spirit of ammonia applied to the wounds of snake bites or rabid animals, is better than any caustic. It neutralizes the virus.

In post-partum hemorrhage try tying a piece of strong webbing tightly above the knee of the patient.

Carbolic acid poisoning can be quickly cured by giving cider vinegar diluted with equal parts of water in half tumblerful doses every five or ten minutes for a few times.

To keep the hand soft after using plaster of Paris, carbolic acid, etc., an application on going to bed of ointment composed of melted beeswax, tallow, and sweet oil to the hands will soften them in one night.

Cocaine poisoning is antidoted well by strong coffee.

A daily sponge bath is necessary for the pregnant

woman, in order that the skin does not become inactive and throw its work upon other organs already severely taxed, especially the kidneys.

Potassium permanganate is an efficient antidote if taken while morphine is still in the stomach. Grain for grain it will completely decompose morphine.

A typhoid fever patient will do well upon a diet of rice water.

Ice applied to the external genitals—the scrotum in men, the labia in women—is said to be the best and simplest method for controlling blood spitting and nosebleed.

A baby may be filled up to the neck with milk and still be hungry.

In prescribing infant foods it is worth remembering that rice is an astringent and farina a laxative.

A towel dipped in boiling water, wrung out rapidly, folded to proper size, and applied to the abdomen, with a dry flannel over the hot towel, acts like magic in infantile colic.—M. E. Douglass.

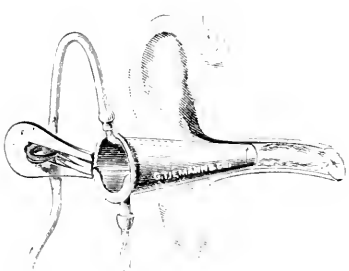
New Instruments.

A NEW DEVICE FOR SYRINGING THE EAR.

By L. G. LANGSTAFF, M. D.,

BROOKLYN, N. Y.

This device may be used for any condition in which it is necessary to syringe the ear. It is attachable to the bag or fountain syringe, to which it may be connected by means of a glass connecting tube or by the small hard-rubber tip which comes with the syringe. The accompanying cut shows its construction and operation so clearly that little in the way of description need be added. Briefly, however, it consists of an ordinary cylindrical metal ear speculum of the middle size. Along its upper wall runs a very small channel which terminates in a small slit-like opening at its inner end, and at the outer end in an expanded portion for the attachment of a connecting tube with the bag. The syringing solution returns through the speculum proper and by means of a tube, if necessary, into a basin supplied for the purpose. This means for conducting the return flow,



A New Device for Syringing the Ear

however, need only be used when the prolonged application of hot water is required. In these cases I take a small section of thick rubber tubing and slip it over the inner end of the speculum so as to prevent the escape of the fluid on the outside of the speculum in the return. To the handle of the instrument is attached a spring cut-off. Pressure by the thumb on this spring allows the fluid to run; removal of the pressure, of course, stops it. The action is instantaneous; there is no slopping or spilling of the fluid. Instead of the fountain syringe I have attached Valentine's irrigator to it after detaching his metal handle with sliding cut-off. For syringing wax from the ear (for which it is very efficient) the convenience of raising the reservoir to a considerable height is of value.

As regards convenience, safety, and efficiency this instrument has entirely fulfilled my expectations. The jet of fluid strikes the upper wall—where it should and spreads out over the walls and drum membranes, thus avoiding direct force on the latter. The stream is continuous and steady, and as it is small a large quantity of fluid is not required. Children submit to this kind of syringing with apparent comfort. The use of the instrument requires no skill and in syringing in a case of a suppurating otitis absolute reliance can be placed on the ear being thoroughly cleansed (an indispensable condition to cure) by the unskilled nurse or by the patient himself. The insufficient cleansing of the ear in suppurating conditions I regard as the most potent cause of delayed cure. The kinds of syringes in use in the hands of our patients are easily accountable for this. No child can be expected to stand the explosive jets of air and water which the ordinary piston syringe produces, i. e., providing the stream goes to the drum membrane at all. There is also the danger of so plugging the canal that there is no room for the return flow, thus forcing in or rupturing the drum head. The risk of doing harm in this way frequently results in the inexperienced nurse doing the work in such a perfunctory manner that nothing is accomplished. The way is thus open to the usual dangerous complications.

The indications for prolonged douching with hot water are fully met by this instrument. With the drain tube attachment a patient may be syringed while lying down. In syringing out wax, the constant strong jet of water directed at one point has an excavating power which soon results in the effectual removal of the wax. As a speculum its value is scarcely impaired, only about one-tenth or less of its lumen being occupied by the inner tube. This feature of the instrument has obvious advantages.

19 Seventh Avenue.

AN IMPROVED TROCAR.

By CARL STRUEH, M. D.,

CHICAGO.

As a means of avoiding an obstruction of the cannula by the bowels, which we meet quite frequently in tapping the abdomen and which necessitates the introduction of a sound in order to push the bowels away from the cannula, it is advisable to provide the upper end of the latter with a number of perforations, as is shown in the accompanying illustration.

These perforations make any obstruction of the cannula impossible and allow as complete a draining of the abdominal cavity as is possible under any circumstances.

The strength of the cannula is not impaired by these perforations, if the latter are not larger in size than the head of a pin.

464 Belden Avenue.

Suprarenal Extract in Ear Diseases.—Dr. W. H. Bates (*Hot Springs Medical Journal*), says that we have no remedy so useful for the relief of deafness. Acute cases have been permanently relieved in one treatment. Chronic cases are temporarily improved and require other treatment to obtain permanent results. The remedy is indicated in all forms of deafness, and this author has not met a case which was not benefited temporarily. The method of administration is important and one must use freshly prepared solutions. 1. The solution of the extract is syringed through the punctum of the lower lid down the nasal duct and allowed to flow over the orifice of the eustachian tube. This is repeated until the hearing is no longer improved. 2. The extract is applied to the inferior and middle turbinated bodies until the nose is widely opened. 3. A few drops are syringed into the tympanum through a puncture of the membrane tympani. This method does not usually improve the hearing. 4. The internal administration of 5 grains three times a day should be employed in chronic cases, as it is often beneficial. After the hearing has been improved by the suprarenal temporarily, nitrate of silver applied to the eustachian tube is followed by more permanent benefit. Bloodless operations are performed on the middle ear with the aid of suprarenal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 6, 1901:

	Cases	Deaths
Measles	274	10
Diphtheria and croup	251	54
Scarlet fever	370	30
Smallpox	67	15
Chickenpox	40	
Tuberculosis	230	140
Typhoid fever	53	10
Cerebro-spinal meningitis		3

Tenements in London.—During the past fifty years London municipalities have constructed dwellings containing some 6,132 rooms, whilst organized private action has, in the same period, provided buildings containing 50,402 rooms. This total is by no means exhaustive, since it does not take into account certain semi-suburban dwellings, and could not take note at all of all the work of private associations. In an examination of the cost and rent of tenements, Dr. Sykes has stated that the cost of construction varies from £4 ($20) to £40 ($200) per room, for cost of goods, site and sewers, whilst the cost of building varies from £35 ($165) per room in the country to £135 ($675) in London County Council tenements. There has been an enormous increase in the cost of building in London of recent years, and wages in six years have risen from twenty-five to thirty-five per cent., whilst the hours of labor have fallen ten to twelve per cent.—*Public Health.*

Some Points in the Cure of Constipation.—Sir James Sawyer, of Birmingham, England, read a paper on this subject at a recent meeting of the Leicester Medical Society. Habitual constipation, he said, had long engaged his attention, as he took it to be a subject worthy of deep consideration. Constipation must not be confounded with intestinal obstruction. The former concerns the large intestine only, the latter the whole tract, small as well as large. Constipation is slow fæcal passage through the large intestine, where alone fæces are to be found. Intestinal obstruction is practical interference with the passage of the contents in any part. Constipation prolonged may determine organic obstruction, koprostasis, fæcal stagnation. The human fæces consist of a pasty mass of insoluble food, mixed with pancreatic secretion and mucus, colored by bile, and shaped by the intestine. Fæces, besides the above, are more; they are in part an excretion the removal of injurious products. Excretion and the formation of fæces go on when no food is taken, in starvation and fever. People indulge in manifold errors of habit and effort, by altering which many forms of constipation can be relieved. We should all try these methods, before having recourse to drugs and enemata. Patients always wish for a strong purge, but they should be educated to a more reasonable idea. The following rules should guide the medical practitioner: 1. We should never leave these things to our patients; all should be under our control. 2. We should never give drugs until constipation cannot be cured without them. 3. We should never give drugs without well-regulated adjuvants of alvine relief.

The steady use of purgatives shortens life. This is felt when, after the climacteric, the bowel refuses to respond, and chronic constipation results. This may mean ten years off the life of an ordinarily healthy individual. Habitual constipation is a penalty of civilization due to neglect of the desire, due to defecation on a seat, to diminution in activity of the abdominal and respiratory muscles, and to abstinence from fruit. It should be a rhythmical act, once in twenty-four hours, at a fixed time, best after a meal, whether there be want or not, at other times, whenever there be a want, it should never be put off. Resisting the desire drives back the fæces into the sigmoid flexure, by contraction of the rectum, where they can be tolerated. Cancer of the sigmoid may be determined by chronic irritation. Most women are habitually constipated, a condition due to lack of effort, and to the pressure of stays, causing feebleness of the abdominal muscles, besides mechanical obstruction in the ascending and descending colon. In pendulous belly an abdominal belt is useful. The natural position in defecation is that of a child with the knees touching the back of the arms. It is the best position for the abdominal muscles to act, and the hernial orifices are closed. This position may give relief when other measures fail. Women with fat nates have especial difficulty when using a seat. The seats of water-closets are generally too high, and should be lowered by at least six inches. Respiratory exercises before breakfast and dinner are of use: 1. To exert pressure on the liver, place the heels together, raise the arms at right angles to the body and rotate them backwards and forwards, two or three times. 2. Separate the feet, raise the arms and sway from side to side until the hand touches the leg below the knee. 3. The chief points of accumulation are the cæcum and the sigmoid; these parts may be compressed by the psoas and iliacus muscles by standing beside a table and putting first one foot and then the other on it.

Foods: Green vegetables should be taken; fruit, especially apples (cellulose excites peristalsis), and marmalade are excellent for breakfast.

Drugs: Each person has his favorite. Sawyer personally preferred aloes and considered that belladonna and nux vomica were of little use: He was wont to prescribe the following:

℞ Aloës Socotrin ..... gr. i, ii, or iii.
Ferri sulph. ..... gr. ½.
Ext. hyoscyami ..... gr. i.
Ft. pil. t. p. i. n.

The quantity of aloes requires readjustment, generally reduction. Sometimes when a patient is impatient, one must give a drug and turn to adjuvants later. This should be done also in cases of atonic condition with dilated and loaded bowels. Salts and senna, carraway seeds, raisins, and figs are frequently very useful.—*Quarterly Medical Journal.*

Health of European Troops in India.—The statistics of the European Army bear evidence to the healthiness of the year, and the absence of war, in greatly reduced sickness-rates and a comparatively low death-rate. The latter was 12.75 against 20.05 in 1898 and 10.40 in 1889-98. Venereal diseases and ague, were, as usual, the chief causes of admissions, and typhoid fever and hepatic abscess, of deaths. There was only one case of cholera in the whole army—an unprecedented experience. An interesting table shows the mortality from cholera, during the last twenty years in quinquennial periods, indicating a gradual reduction, which is not shared by native troops, prisoners, or the general population. The admission-rate for ague was low, also for remittent and simple continued fever. There was a great decrease both of morbidity and mortality, from typhoid fever. The rates were 20.6 and 5.14 against 36.9 and 10.17 in 1898. The reduction is attributed to the healthy year, fewer drafts, and no field service.

There were eighty-three cases of scarlatina with six deaths, most of which were traced to infected transports. There was a slight rise in tubercle mortality, but other respiratory diseases were not in excess. There was a considerable abatement in fatal bowel complaints. Hepatitis was less common and the mortality from liver abscess was somewhat reduced. The admission rate for venereal diseases was 313.4 against 362.9 in 1898 and 185.7 in 1897. The diminution is explained by the treatment of men with venereal diseases as out-patients, the effect of the new Cantonment Act, and the more prolonged treatment of the cases. There was a great reduction in heat stroke, due no doubt to less exposure and fatigue. Seven cases of plague occurred in four Bombay Stations, with two deaths. The death-rate of officers of the British Army was 8.81, and of the Indian Army 7.36, of women 14.55 and of children 41.99—all better than the average. —*British Medical Journal.*

Opium in India.—According to a statement made by Lord George Hamilton, the area under poppy cultivation in Bengal in 1898-9 was larger than any other year of the decade, and the quantity of opium produced was considerably larger than it was in the preceding year.

Lethal Effect of Yew—The sudden death of a patient, says the *Medical Press*, in Mullingar Asylum from eating yew (taxus baccata) leaves arouses attention to the inadvisability of ornamenting the recreation grounds of asylums with plants and trees of well-known lethal properties. To both men and animals the yew is poisonous, as has been noted by classic writers including Cæsar, Virgil, and Livy. Bentley and Trimer state that the leaves and young branches in all circumstances act as a narcotic acrid poison. Numerous cases of poisoning are recorded in medical literature, as may be seen by reference to works on forensic medicine. That fatal results do not occur more often from the use of the leaves is greatly to be wondered at, for the tree is common throughout the three kingdoms, and they are a favorite domestic remedy for worms, female irregularities, and less seldom as an hypnotic. At one time was recommended in the treatment of heart disease as a substitute for digitalis, over which it was said to possess the advantage of not being cumulative in its effects. In India the fruit and leaves were credited with antilithic properties, and some native physicians claimed litholytic properties for them. As a remedy for convulsions in children and for epilepsy in adults, the infusion of the leaves was once freely prescribed. Their active toxic action would imply that they possess properties that are well worth physiological examination, and they may possibly become a valuable addition to our therapeutic remedies. At present we practically know nothing more than that the tree yields a powerful poison for man and beast, and such knowledge is sufficient to warrant its exclusion from all places where the insane, children, or cattle may eat it.

The Sanitation of Health Resorts and Country Houses.—It is a duty which dare not be neglected to call public attention to the fact that many so-called health resorts are more insanitary than our crowded, smoke-grimed, steam-sodden factory towns. It is not the large popular seaside or "spa" town which is so much to blame in this connection, as the newly-born and pretty little seaside village, which had been discovered and had had greatness thrust upon it by railway companies and excursion agents before it was really prepared to start housekeeping on its own account, and has no such thing as a sewerage system or a water supply, and perhaps no engineer to prepare either. The man with a large family is easily lured into sending the said family to such a place, or perhaps to one of the many advertised country farmhouses or cottages, with never a thought of inquiring into anything but the rental. It is not too much to say that the average "small country-house to let during the summer months" is a danger trap, which should be most carefully examined before it is entered. Adults do not suffer from the bad conditions of such houses or "health resorts" to such an extent as children, for they can wander abroad more and their constitutions are firmer; but what a common experience it is for parents on returning home from such places to exclaim with amazement that they cannot understand their child being ill, because it has come back from the seaside or the country only a few days ago! The preventive remedy for such things at present is for parents to get their medical man to make inquiries from the local medical officer of health as to the sanitary state of the place in which they propse to spend their holidays, and to be guided by his advice. But surely it is a matter in which the government might interfere by prohibiting the letting of houses for holiday purposes, unless such houses have previously been certified by the local sanitary authority to be free from all conditions dangerous to health.—*Medical Magazine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, United States Marine Hospital Service, during the week ended June 29, 1901:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
California, Los Angeles	June 15th to 22d	1	
District of Columbia, Washington	June 15th to 22d	1	
Indiana, Evansville	June 22d	1

HYDROPHOBIA, AND THE PASTEUR METHODS.

BY CHARLES WINSLOW DULLES, M.D.

PHILADELPHIA.

LECTURER ON THE HISTORY OF MEDICINE, UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS; AND FELLOW OF THE ACADEMY OF SURGERY OF PHILADELPHIA, ETC.

WHOEVER is familiar with the history of medicine knows of curious changes in the way in which certain subjects have been considered. There was a time, for example, when the diseases of the human body were attributed to supernatural, or rather superhuman agents; afterwards they were attributed to changes in the material parts of the organism; at another time they were attributed to changes in the spiritual essence with which it was believed to be infused, while now the general theories of disease are in accord with the prevalent materialism. Likewise the whole conception of disorders changes from time to time, so that it is with difficulty that we get a clear idea to-day of what some of the older writers intended in their descriptions. This, which has taken place in the large field of medicine, and in long ages, sometimes proceeds more rapidly, and a few years suffice to put old observations and theories in new and strange lights. This is the case in regard to what for many centuries has been called hydrophobia. There was a time when, to write intelligently on this subject, one could follow the plan usual with scientific students, of collecting facts, analyzing and comparing them, and deducing conclusions as the result of a logical process. But since about fifteen years ago this has been changed. As Mohammed swept before him those who questioned his divine authority, so has the school of Pasteur, followed by an admiring, if not a critical, multitude, swarmed over the face of the scientific world, brushing aside all the knowledge in regard to rabies accumulated before its day and reducing to a small remnant those who think that the sneering epithet of "obscure blasphemers" hurled at them by one of the blindest of Pasteur's advocates (Verneuil), can be borne better than the abandonment of what they regard as the truth and the proper way to determine the merits of a scientific question.

Under existing circumstances, I will not to-day repeat or add to what I have often before done, by presenting a methodical study of the history of hydrophobia, of its nature, of its pathology, of its diagnosis, or of its treatment. I shall rather state some facts, bearing on the merits of the claims of the followers of Pasteur, that I think are not known to all who wish to hold sensible opinions in regard to the nature of hydrophobia and its management.

Fifteen years ago I published[1] an elaborate criticism of the way in which Pasteur arrived at the conclusions he gaily announced to a correspondent of the *Paris Figaro*, as follows: "Anybody bitten by a mad dog has only to present himself at the laboratory of the Ecole Normale, and by inoculation I will make him completely insusceptible to the effects of hydrophobia, even if bitten subsequently by any number of mad dogs." Later he said: "Whoever gets bitten by a mad dog has only to submit to my three little inoculations, and he need not have the slightest fear of hydrophobia." And, again in reliance on his brilliant assumptions: "I am confident my treatment will be successful if commenced at any time before actual hydrophobia sets in, even if a year elapses between the bite and the commencement of treatment."

It is curious to note that all these boasts have been abandoned with a quietness in marked contrast to the trumpetings with which they were announced. The Pasteur treatment has never rendered a single person "insusceptible to the effects of hydrophobia;" there are now no "three little inoculations;" and the large number of deaths following the application of the Pasteur method soon led to the remarkable evasion contained in the plea that deaths occurring during or within fifteen days after the conclusion of the treatment were due to the fact that it was used too late. In passing, the observant reader may inquire, what it is that so shortens the incubation of a disease that rarely manifests itself in periods as brief as have sufficed to see the end of many who fled from it to the refuge offered by Pasteur Institutes?

These failures in what Pasteur claimed are the more distressing when we reflect that for them he had abandoned a much safer and better way of ridding the world of hydrophobia, namely, by eradicating the disease in dogs. Only a year before at the Inter-National Medical Congress at Copenhagen he, while on the platform, received a timely telegram from Paris announcing the complete confirmation by a French Commission of his claim to have discovered a sure method of protecting dogs against contracting rabies from bites. Amid shouts of applause he read this telegram to the audience and accepted the homage of those who did not know—as I know, by carefully analyzing the report of the Commission[2]—that of forty-two experiments reported only two—so far as the report informs us—were carried to a conclusion, and that there is no evidence in the report of the fact that the members of the Commission were free from the idolatrous credulity with which Pasteur at that time inspired the French or exercised any such care as was needed in so important and delicate a matter. The positive terms in which this Commission endorsed the claim of Pasteur that he could protect dogs against contracting rabies might well fill the hearts of those who listened with hope for mankind and with admiration for its benefactor. But, alas! I cannot find that from that day this sure way of removing

[1] Comments on Pasteur's Method of Treating Hydrophobia, MEDICAL RECORD, Feb. 13, 1886.

[2] *Gazette Hebdomadaire de Méd.*, Août 15, 1884, pp. 547-549.

hydrophobia from the earth has ever been put in practice. And the disillusion—did it come? Not in the least! The fiasco seems to have escaped the attention of the medical profession, lost in wonder at a new claim of this master of pyrotechnics. This new claim was that he had discovered, as stated above, another "sure" method, namely, that of preventing the outbreak of hydrophobia in persons bitten by rabid animals.

This announcement, like the one before mentioned, was hailed with acclamation, and those who had not detected the flaws in Pasteur's reasoning, the contradictions in his statements, and his failure to carry out projects that he had outlined, greeted him with most extravagant terms of praise. In this country some of his admirers, with misguided zeal, hastened to follow his lead in such ways as their varying ignorance of the matter suggested. For example, in December, 1885, a New York admirer endeavored to propagate the fancied germs of hydrophobia, cultivated in glycerine and agar, and the first "American Hydrophobia Institute" was organized, with well-known names back of it. At the same time, a similar institute was started in St. Louis, absurdly promising to be prepared to treat all comers within three weeks. These institutions seem to have perished at birth or soon after; and it was some years before a French immigrant established a Pasteur Institute in New York, while another foreigner set up one in Chicago. About three years ago a third was opened in Baltimore, where there had been some disappointment because four persons out of eight, sent to the New York Institute in December, had died within about two weeks of the time of their treatment. In other lands Pasteur Institutes have been established in such numbers that I know of more than twenty such institutes in different parts of the world.

I have endeavored to learn what have been the actual results of the Pasteur treatment on the mortality from hydrophobia, and I am sorry to say that these results entirely agree with the expectations I had formed from an abstract consideration of Pasteur's work. It has been claimed that a very large number of lives have been saved, and comparisons emanating from Pasteur Institutes—and often cited by persons with a very superficial acquaintance with the facts—make it appear to the unwary that before the inauguration of this method the mortality from hydrophobia was one to sixteen, sixteen per cent, or even fifty per cent. (taking different Pasteurian authorities), while the mortality has been reduced by the treatment to about one-quarter of one per cent. In a circular issued in 1899 Pottevin claimed that at the Pasteur Institute in twelve years there had been treated 21,631 persons bitten by animals. Of these, he says, only ninety-nine have been lost. "That is 21,532 human lives that Pasteur and his disciples have saved." Well may Lutaud[3] exclaim: "So the directors of the famous Parisian Institute have the audacity to try to make us believe that, without the discovery of the great Pasteur, 21,631 persons would have succumbed to hydrophobia and that in France alone." And, shall we blame him, when he says that such a statement is not an audacity—but a lie?

These absurd and false statements I have repeatedly criticised in public addresses; but these criticisms fall on stony ground when addressed to men whose minds accept as trustworthy figures that imply that, but for the Pasteur method, the deaths from hydrophobia would, in the years succeeding its establishment, have multiplied enormously beyond anything known in previous history. The last time I made a statement of this kind to a medical society that I had been invited to address, one of its most distinguished members joyously told the society that I knew nothing about the subject, and another, equally distinguished, met my statement that deaths from hydrophobia had not decreased but increased in France, by reading from a slip of paper statistics purporting to show a progressive and rapid decrease in the mortality. The latter fell into error—which he soon after admitted to me in writing—by quoting at second-hand a statement made by one connected with the Pasteur Institute in Paris that referred, not to the mortality from hydrophobia in France, but to the claim for a comparative reduction in the mortality among persons subjected to Pasteur's preventive inoculations.

The fact is that I find, in going over the work of a number of Pasteur Institutes, that hydrophobia has proved to be a more fatal complaint since their establishment than it was before. I have in my notes a memorandum of the deaths from hydrophobia in the city of Paris for the five years preceding and the five years following the inauguration of Pasteur's methods. The figures are taken from reports of Dujardin-Beaumetz to the Academie de Médecine[4].

This will be seen to furnish, for the years 1880 to 1884, forty-three deaths, and for the years 1885 to 1889, fifty-nine deaths. In addition to this, a large number of deaths followed the Pasteur treatment which are not included in these statistics. The figures vary from year to year in the two lustrums referred to above, but the only material difference between them is that in the first we have four deaths for the lowest and twenty-one for the highest, while in the second we have three for the lowest and twenty-two for the highest—the latter being for the year in which the Pasteur method was brought out, when the largest advertisement of it was made in the newspapers of Paris, when everybody was talking about it all over the world, and when cases of lyssaphobia multiplied everywhere in consequence of this morbid discussion. So marked was the increase in deaths from rabies among animals at this time in France that I find Nocard,[5] in 1888, speaking to the Academie de Médecine of Paris of the cases occuring in Paris, says that a like increase was observed "everywhere in France;" while in 1892 Galtier declares[6] to the same body that hydrophobia has "singularly increased."

I have recently studied with interest the statistics given in an elaborate work on hydrophobia by Dr. A. Högyes,[7] of Budapest, who is at the head of the Pasteur Institute in that city. After citing some of the imperfect statistics of previous years giving the annual mortality in different countries as follows: Prussia, 19.5; Bavaria, 3.5; Belgium, 2.6; England, 10; Scotland, 1; Sweden, 5.8; France, 30; Hungary, from 1809 to 1818, 25, he sets down the annual mortality in Hungary, from 1881 to 1885, as 9.6. In connection with these figures it is noticeable that he says the deaths in Hungary were, 22 in 1886; 9 in 1887; and 15 in 1888.

Lustrum preceding:		Lustrum following:	
1880	4 deaths.	1885	22 deaths.
1881	21 "	1886	3 "
1882	0 "	1887	9 "
1883	4 "	1888	19 "
1884	5 "	1889	6 "

In another part of his work[8] he states that the deaths from April 1, 1886, to December 31, 1895, were as follows: Of those submitted to preventive inoculation, 166; of those not inoculated, 132. This is a total of 238 in five and three-fourths years or over forty-one annually. If this is compared with the figures he gives from 1881 to 1885 namely 470 it will be seen that there appears to have been an increase to over four-fold what had taken place before. Another curious feature of his statistics is the fact, that in Germany, from 1880 to 1894, 4,252 cases of actual or suspected rabies occured in dogs and there were only ten deaths in human beings, that is one death to 425 cases observed in dogs. In France he gives a record[9] for the same period of 6,327 cases in dogs, and states that 8,275 Frenchmen were treated in the Pasteur Institute in Paris. On the most moderate estimate of the ratio of mortality to bites accepted by the Paris Institute, this would have furnished 510 deaths, if untreated, or one to about twelve cases in dogs. In other words, it appears that there is an enormous discrepancy between the ratio of deaths from hydrophobia to cases of rabies in dogs in Germany and that in France—the latter having a mortality thirty-eight times as great.

This great disparity between France and other countries has not altogether escaped the attention of the followers of Pasteur, who, in France, have added to their other evidences of ignorance of what goes on outside of their own country by claiming that the comparative immunity of England, Belgium, Holland, Austria, and Germany is due to the administration of effective muzzling laws.[10]

As a matter of fact, the muzzling laws of England are as inefficient as they are in this country, and those of Germany do not prevent the taking up annually of a very large number of unmuzzled and suspected animals whose opportunities for biting are quite sufficient to cause a large number of deaths from hydrophobia. The contrast between Germany and France is further shown by the statement that in Prussia there was, in 1895, not a single death from hydrophobia, though 386 cases of mad dogs were reported, and 906 suspected animals in addition were killed by the police.[11]

I will not pursue further this line of argument. I think a conscientious examination of the statistics of every country where Pasteur Institutes have been widely exploited will show that the deaths from hydrophobia have actually increased.

One way in which this comes about is that the men at the head of these institutions, in addition to making unwarranted promises of cure, sometimes make equally unwarranted prognoses of fatal issue. In some cases these prognoses may be fairly assumed to exert a most unfavorable influence upon the patients, in other cases the patients recover in spite of them, and thus expose the ignorance as well as the lack of conscience of those who have been made them.

It is probably generally not known that in different parts of the world men with no interest whatever except the good of their fellow-beings have raised their voices in protest against the unprincipled assertions and behavior of those who have been most active in propagating the Pasteur theory in regard to hydrophobia. It will not do for the advocates of this theory to attempt to depreciate the force of what these men say by intimations that they are inferior in intelligence to those who have gone with the heedless [illegible]. In France [illegible] very beginning, the good and great Pr[illegible] tested against the mania which su[illegible] countrymen in regard to Pasteur[illegible] Lutaud, Editor of *The Journal de M[illegible]* has unremittingly and conclusively exp[illegible] *Journal* and in a book on the fallacies an[illegible] ing falsehoods put out by persons connected with the Pasteur Institute in Paris, while in England, Dr. Thomas M. Dolan, for years an investigator of the subject of hydrophobia and author of several books on the subject, has exposed the Pasteur theory in a carefully prepared book[12] and Surgeon-General C. A. Gordon of the British Army has written a book[13] in which he exposes many of the fallacies put forth as argument by Pasteur and his followers.

In my long experience as a controversialist on this subject, I have failed so far to find a supporter of Pasteur who showed any practical acquaintance with the arguments of these authors. They all seem to have been satisfied with the presentations of the case which came from persons devoted to the Pasteur theory; while those who are opposed to the Pasteur theory are far more accurately acquainted with the whole body of assertions and arguments of its defenders than any one of them appears to be.

The most recent publication illustrating this particular weakness is a report on Rabies by the Committee on Public Health of the Medical Society of the District of Columbia, issued in 1900 by Dr. D. E. Salmon from the Bureau of Animal Industry in the United States Department of Agriculture. In this I observe a number of what might be called "conventional" loose statements—so regularly are they repeated without any attempt at verification by the devotees of the Pasteur theory—and especially Pasteur's utterly unwarranted and false statements in regard to the mortality rates after bites of rabid animals, and the relative mortality after bites at certain ages and after bites upon certain portions of the body. After nineteen years of assiduous studying of the various aspects of the subject of hydrophobia, I feel warranted in expressing the opinion that there is no more conspicuous mark of unfitness to discuss it than the credulity which accepts statistics put out by a number of so-called Pasteur institutes with the constructions placed upon them by their collators, or the cowardice which prevents disputants from challenging what comes from sources that they know to be tainted with fraud. Some of these points I discussed in a paper published in 1894.[14] In this paper—which is accessible to any one who wishes to employ it for his information or who wishes to correct its statements in proper scientific fashion, I have stated the results of my personal investigation in regard to the points just named, and have compared them with the findings of other investigators. From this paper I quote the following statements.

"In regard to the relation of the period of incubation to the age of the patient and the situation of the bite, the statistics of the United States for the last six years are, I think, very instructive. They indicate precisely what is found upon studying the thousands of cases reported in books and medical journals which I have investigated, namely: That the facts do not in the least support the theory that bites near the center of the nervous system are more dangerous or more likely to be followed by a brief period of incubation than those inflicted on more re-

mote parts. In our statistics we find a child four years old bitten on the face, with an incubation-period of nearly five months, and a man thirty-five years old bitten on the hand, with an incubation-period of only four weeks. We have also a four-year-old child bitten on the finger, with an incubation-period of three weeks, and an adult bitten on the leg, with an incubation-period exactly the same. Taking all the cases together, we find that after bites on the face the incubation-period was less than the time-honored quota of six weeks in only a third of the cases, while the same is true of a full fourth of the cases of bites on the hand and wrist. These facts correspond to what other statistics show. Nobody can predict the length of the period of incubation, even approximately, from a knowledge of the seat of the bite or from a knoweldge of the age of the patient. Assertions to the contrary are either pure assumptions or are founded upon averages, which are false and misleading." In the same paper I published the subjoined table:

TABLE OF SITUATION OF BITE, AGE OF PATIENT, AND PERIOD OF INCUBATION.

Face.			*Hand and Wrist.*

7 y'rs	18 weeks		Old	13 "	Total, 24
Adult	3 "				
"	13 "	Total, 3			

This table gave the details of the cases occurring in the United States in the six years preceding 1894.

When I began the study of hydrophobia my views were practically the same as those of conservative writers in the text-books; but I soon became impressed with the insufficiency of the evidence I found to establish the fact that hydrophobia is a disorder which can be regarded as specific in the sense in which this term is properly employed. I know that a fairly consistent train of symptoms, usually ending in death, has followed the bite of dogs believed to be rabid; but the study of a very large number of cases has left me with the conviction that this is about as likely to follow the bite of a dog that could not be suspected of being rabid. In 1895, in a report to the Medical Society of the State of Pennsylvania,[16] I said:

"I have, since we last met, made a study of my records for five years of what I have labelled "mad dog scares" in my notes. The result of this study indicates that in fifty-five instances of alarms about mad dogs, with a record of one hundred and seventy-five persons (of all ages) bitten, I have found only three deaths from so-called "hydrophobia." This, if correct, would indicate that the natural mortality from the bites of rabid dogs is 1:58, or less than 2 per cent. The vast majority of the deaths attributed to hydrophobia have followed bites by unsuspected dogs, and very few have followed bites by dogs that ran amuck and that excited alarm at the time. It is a very curious fact, taken in connection with this one, that a very large number of the deaths from so-called hydrophobia follow the bites of dogs that had no history or appearance of any disease.

"The number of cases for the past year is about what I have before reported for other years. The total probably does not include all the cases that have occurred in the United States; but I think that it represents the actual figures as accurately as the statistics attainable in other countries, without government assistance in the work of collecting statistics. Against this number of actual deaths we may set the absurd claims put out by Pasteur institutes of so-called "cures." Last year the institute in Paris treated 1194, all supposed to be liable to die of hydrophobia; and these figures will probably be used to support the assertion copied into books all over the world, that Pasteur has reduced the mortality from hydrophobia to less than 1 per cent. of those bitten by rabid animals. It is astonishing and disheartening to find men occupying responsible professorial positions who fail to see the utter fallacy of such claims or to appreciate the wrong they do by accepting and approving them."

So much in regard to theoretical considerations. I wish at this time to add a word or two about the practical application of my convictions. I have noticed in some recent publications in regard to rabies, insinuations that those who did not share the opinions of the Pasteur followers should be held responsible for the ravages of this dreaded disorder. Perhaps I have no reason for championing those who are thus referred to beyond the fact that if my own views have not escaped notice it may be that those who do not agree with them—in addition to holding views that I regard as unwarranted by the accessible evidence—do not know that I am quite in favor of the measures which their own school has praised as most useful in preventing hydrophobia, namely: the proper muzzling of dogs. In May, 1900, in reply to a letter from one of the Commissioners of the District of Columbia, asking my opinions in regard to the enforcement of a regulation for muzzling dogs, I said: "I favor a dog-muzzling law and its thorough application:—First, because I consider it proper to adopt any reasonable measure to allay a fear which is genuine, even though it be exaggerated. Second, because the most innocent attacks by dogs are sometimes followed by most disastrous consequences. If a so-called rabid dog is little more dangerous than a healthy one, it is equally true that a healthy dog is little less dangerous than a rabid one. And I think the community should have full and constant protection against dog-bites, irrespective of questions in dispute about hydrophobia." From this it will be seen that I consider the most important measure for limiting the ravages of this disorder—no matter on what theory it may be accounted for—would be the removal of causes of alarm in regard to it.

Finally, I desire to repeat what I have publicly said a number of times and what I wish could be properly appreciated by the profession: I fear we shall never have a correct idea in regard to what is called hydrophobia or success in managing it until the profession wholly abandons two measures the pernicious influence of which no one can understand without years of continuous study, namely, the use of caustics, and especially of the nitrate of silver in the treatment of suspected bites, and the use of narcotics and violent restraint in the management of the fully developed disorder.

THE ETIOLOGY OF ALOPECIA.*

BY DELOS L. PARKER, M.D.,

DETROIT, MICHIGAN.

LECTURER ON MATERIA MEDICA, DETROIT COLLEGE OF MEDICINE.

At a meeting of the American Medical Association in 1899, I read a paper on the subject of alopecia, in which I advanced the theory that the form of this disease commonly met with in male adults, is caused by a poisonous material circulating in the general blood current.

I further stated that this pathological condition is the result of an auto-infection, in which the offending substance is absorbed by the blood from the air-cells of the lungs, where it has been elaborated by decomposition of the organic material normally present in respired air.

In this paper it is my purpose first to explain the particulars of this same theory, then to call attention to the seeming completeness with which it accounts for the presence or absence of alopecia among certain classes of individuals, and finally to give the results of a series of experiments based upon it and applied to various animals.

Along with all this, by implication, however, rather than by direct statement, it is hoped that attention will be drawn to a locus of infection in the human body that, in the opinion of the writer, has not been accorded the consideration its importance seems to call for.

The Theory.—In order to explain the nature of the theory, it is necessary first to recall to some extent the anatomy of the human thorax and lungs, and to touch upon some features of the physiology of respiration.

The thorax is a framework consisting of bones securely joined together by muscles and other tissues, and in shape may be said to be a truncated cone.

The ribs, which form the chief part of the vertical portion of this cage, are attached to the bodies of the dorsal vertebræ by arthrodial or sliding articulations, and, as they pass around to the front of the chest, gradually increase in length from the first to the seventh, after which they gradually shorten. Also, beginning with the first, which lies nearly horizontal, the ribs gradually increase in downward obliquity until the ninth is reached, below which this characteristic becomes less marked.

The diaphragm, which forms the floor of the thoracic cavity, is attached anteriorly to the cartilage of the sixth rib, a fact which lets us see that the thorax itself is a cage with a gradually increasing circumference from top to bottom, and also, in the same order, with a gradually increasing downward slope of the ribs, which form the chief part of its wall.

The inside of the thorax is lined, on each side, with the parietal layer of the pleura of the corresponding lung, which is adherent to the ribs, cartilages and intercostal muscles, and to the diaphragm. Beneath this membrane is the visceral layer of the pleura, which is lightly adherent to the lungs itself. There is between these two layers of pleura the so-called pleural cavity, but in health this space is so small that the two layers may be said to be in close contact with each other, and kept so by the atmospheric pressure of fifteen pounds to the square inch. The object in calling attention to the lack of space between the parietal and visceral pleura is to emphasize the fact that in health the lungs, although not actually attached to the thoracic wall, are yet intimately moulded to its inner surface, and that they continue persistently to maintain this relationship, whatever be the frequency or extent of changes in the shape or size of the thorax itself.

Respiration, for the accomplishment of which the structures just referred to have been provided, can be separated into inspiration and expiration. Inspiration is produced by muscular exertion elevating the down-sloping ribs, or depressing the piston-like diaphragm, the result of either of these procedures, or of both combined, being to enlarge the chest cavity and thereby cause air to rush through the trachea into the lungs, in conformity with Nature's edict concerning the existence of a vacuum. Expiration, on the other hand, is produced, not by muscular effort, but by gravity and the elastic property of the tissues of the lungs themselves. These acting together exert sufficient force to bring the chest back to its contracted condition as soon as opposing muscular stress has been removed. In forced expiration, muscular exertion, of course is called into requisition.

Besides a separation into its component parts, respiration can be classified into types which are based respectively on the part of the thorax chiefly involved in each one's production. Thus when the upper ribs take an active part in the process of expanding the chest, so as to produce inspiration, the breathing is said to be of the *superior costal type*.

When, on the other hand, the lower ribs and diaphragm take an active part in this function, while the upper ones remain immovable (a condition always possible on account of the origin and insertion of certain muscles, such, for instance, as the musculus accessorius ad sacro-lumbalem), the breathing is said to be of the *inferior costal type*.

Finally, when the diaphragm alone is concerned in carrying on the function under consideration, the breathing is said to be of the *diaphragmatic* or *abdominal type*, the latter name being given on account of the movement imparted to the anterior abdominal wall when this mode of respiration is employed.

Turning our attention now to the lungs themselves, we find that they contain hundreds of millions of hollow minute spaces called air-cells, which in size vary from 1-200 to 1-70 of an inch in diameter and which combined present a surface from 100 to 130 times greater than the superficial area of the body. These air-cells are assembled in distinct masses or groups about the dilated extremities of the bronchial tubes, so as to form so-called lobules.

A crude representation of one of these lobules may be made by comparing it to a bunch of hollow grapes, which, at its center, has an elongated cavity that connects with each grape by a small opening and with the main trunk by a hollow stem.

The lobules themselves, closely invested externally with blood vessels, lymphatics, and nerves, so that each lobule may be regarded as a complete lung, a fraction of an inch in diameter, are placed close to each other throughout the lungs, and are held securely in position by a network of areolar fibrous tissue.

On account of this arrangement of the lobules air within the lungs is held in small sacks, so to speak, which are connected by small tubes, of greater or less lengths, with a common cavity extending outside the body, and from this circumstance there results a condition of great importance.

This is, that *air is received or expelled from any part of the lungs only as there is, at the same time, expansion or contraction of the chest wall overlying the part in question;* and conversely *when there is no movement of a portion of the chest wall there is no air received or expelled by the air-cells of the lungs lying beneath the portion of chest wall under consideration*; and all this, in both instances, without regard to the amount of air that may be in the lungs at the time

*Read at a meeting of the Detroit Academy of Medicine, June 11, 1901.

A practical demonstration of the principle involved may be made as follows. Suppose a number of small bellows to be ranged in a row and connected by their nozzles with the cavity of a tube, which is open at one end and closed at the other, and that force is applied to one of these bellows in such a way as to diminish or increase its size. In such case there is disturbance of the air in its own interior and of that in the tube with which it connects, but not of the air in the bellows left unacted upon. The reason for the latter statement is that the air in these bellows is enclosed in dead ends, so to speak, and air rushing past the openings by which they connect with the tube can at most do nothing more than create small eddies in the air of their nozzles—an effect that can cause no appreciable disturbance of the air in the bellows itself.

Each lobule of the lungs, with its bronchiole, 1-70 of an inch in diameter, connecting it with a larger tube, may be compared to one of the bellows above described, and like it will have its enclosed air disturbed only when its own bulk is increased or diminished by outside force.

An application of the rule we have just been endeavoring to establish to the different forms of respiration above mentioned gives the following results: When the superior costal type of respiration is employed, air is received and expelled by every part of the lungs. The reason for this is that, in this form of breathing, the upper ribs rise during inspiration and, in so doing, necessarily lift up the others, since all the ribs are connected together; and during expiration all the ribs descend together, for the reason that gravity and elasticity of the lung tissue, the forces concerned in this portion of the respiratory act, affect all alike.

When the inferior costal type of breathing is employed, however, a different condition prevails. In such case there is no movement of the extreme upper ribs, and in consequence of this and in accordance with the rule just formulated, there is no air received or expelled by the portion of lungs lying beneath the motionless upper ribs.

And when the abdominal type of respiration is employed, a form of breathing in which there is practically no movement of the ribs, the feature that forms the chief result, when the superior costal is supplanted by the inferior costal type of respiration, becomes still more pronounced.

Considering the foregoing we can say that, when the respiration of the human individual changes gradually from the superior costal to the abdominal type, there is developed, fairly early in the process, a condition wherein the extreme upper portion of the lungs neither receives nor expels air with the respiratory act; and further that, as the transition in the type of breathing goes on toward its limit, the extent of this area of unused lung becomes larger and larger, and finally reaches its greatest radius when true abdominal breathing has become established.

In a given case it is probable that the extent of unused lung is not fixed, but is one that varies considerably under different influences—such as exercise. Be this as it may, it can be said of it with certainty that it is always located at the upper portion of the lungs and that it contains respired air. Reasons for the first of these statements have already been given. The second depends for its proof on the fact that after the lungs uncollapse, so to speak, at birth and receive into their interior the breath of life, they never again return to an airless condition except as a serious complication of disease. To ascertain the amount of air left in the lungs at the end of expiration we have to turn to our physiologies again. According to these the amount of air expelled in ordinary quiet respiration is but ⅓ of what the lungs contain. This lets us see that when a portion of lung is left unused it still contains ⅔ as much air as it does as the end of inspiration.

The air remaining in the lobules and tubes of the unused portion of lungs will be termed respired air, although it must contain much more of the materials normally eliminated by the lungs than the so-called tidal air of respiration, which has rested within the lungs but a comparatively short time.

Now respired air contains, among other substances, *organic matter*. This has been known for years. Austin Flint, Jr., in his "Physiology of Man," published in 1868, says: "The pulmonary surface exhales a small quantity of organic matter. This has never been collected in sufficient quantity to enable us to recognize in it any peculiar or distinct properties, but its presence may be demonstrated by the fact that a sponge completely saturated with the exhalations from the lungs, or the vapor from the lungs condensed in a glass vessel, will undergo putrefaction, a property distinctive of organic substances."

E. T. Reichert in "An American Text-Book of Physiology," published in 1900, comparing expired with inspired air, says: "Expired air is 4.78 volumes per cent. poorer in O; 4.34 volumes per cent. richer in CO_2; it is saturated with water vapor, and is of higher temperature and of less actual volume. In addition expired air contains various effete bodies, such as organic matter, hydrogen, marsh-gas, etc."

In this quotation, attention is directed not only to the statement concerning the presence of organic matter, but also to the assertions that respired air is warm and saturated with water vapor.

Taking into consideration what has been written to this point it can be said that, on account of his mode of respiration, the human individual frequently allows respired air to remain undisturbed in the upper portions of his lungs; and that when he does permit this to happen, there is present, in an absorbing cavity of his body, organic matter in the presence of warmth and moisture—a condition most favorable to the development of decomposition.

Now it is the contention of the writer that when the above conditions have been established long enough for such process to occur, decomposition of the organic matter present always does take place; and that, as this retrograde change goes on, a product is elaborated, which being taken up by the blood, exerts a selective poisonous action upon the growth of the hair, and thus becomes the cause of the form of alopecia under consideration.

Application of the Theory to Various Classes of Human Individuals—Men and Women.—Simple observation is sufficient to establish the fact that young adult females rarely suffer from alopecia, while males, of a corresponding age, very commonly do so. According to the theory we are endeavoring to establish, this means that the former regularly employ the superior costal type of respiration, while the latter frequently make continuous use of a different mode of breathing. That these are the conditions that actually prevail, the following quotations and statements are presented as proof:

In "An American Text-Book of Physiology," to which reference has already been made, occur these words concerning respiration: "The costal type is well marked in women and the diaphragmatic type in men."

In Dalton's "Treatise on Human Physiology" may be found the following: " . . . in the adult male, in the ordinary quiescent condition, the diaphragm per-

forms most of the work in the act of respiration; and the movements of the abdomen are the only ones which are especially marked. . . . In the female the movements of the chest, and particularly of its upper half, are habitually more prominent than those caused by the action of the diaphragm; and this difference in the mechanism of respiration is a characteristic mark of the two sexes." Further quotations of a similar nature might be made but these are deemed sufficient for the purpose for which they are given.

To investigate the causes for these differences in the type of respiration employed by the two sexes, hardly comes within the scope of this paper. Since, however, the costal type of breathing is developed in women to a degree far beyond what is possible in men, it may not be out of place to glance over some of the reasons involved.

In the first place, the dress of women, of all civilized countries, at least, is such that descent of the diaphragm is greatly restricted, and the consequence, among these persons, the costal type of respiration, is adopted as a matter of necessity.

In the second place, this mode of respiration can be carried on much easier in women than in men, for reasons of an anatomical nature. In Gray's "Anatomy" occur these words: "The ribs, generally, are more movable in the female than in the male." In another part of the same work is the following: "The upper border of the sternum is on a level, in the male, with the lower part of the body of the second dorsal vertebra, and in the female with the lower part of the body of the third." This is equivalent to the statement that the anterior end of the first rib, which is attached to the same portion of the sternum in both sexes, in the female has a range of motion greater than it has in the male, by the thickness of the body of the third dorsal vertebra—a matter of nearly an inch.

Now the greater the distance the anterior ends of the ribs travel, in moving from the oblique toward a horizontal position, the greater the expansion of the corresponding portion of the chest, or what is the same thing, the greater the disturbance of the air contained in the lungs lying beneath.

Considering the foregoing, we can say that, on account of dress and also on account of great mobility and range of motion of the ribs, women regularly make use of an exaggerated form of upper costal breathing; while men, on account of absence of obstruction to descent of the diaphragm, and also on account of limited mobility and range of motion of the ribs, frequently make no use of this type of respiration.

In this connection, the writer can state that, within the past few years, he has seen three young adult women suffering from alopecia, and that in each of these cases the disease followed an attack of pleurisy or pleuro-pneumonia, accompanied by painful adhesions, which interfered with superior costal breathing.

Adults Suffering from Pulmonary Tuberculosis.—Common observation, as well as the writings of numerous medical authorities, shows that these unfortunate individuals, as a class, not only are not affected by alopecia, but on the contrary, are usually rendered conspicuous by the luxuriance of their hair growth.

The theory under consideration explains these conditions in the following manner. In tuberculosis of the lungs the disease is usually located at the apices. When this is the case, the only part of the lungs where air can remain stagnant is either solidified by the pathological process present, or the absorbing power of the walls of the air-cells is rendered nil by the same agency. And when the disease is located in some other portion of the lungs, the demands of the system for compensation to make up for loss of lung tissue, brings into action all portions of the lungs remaining unaffected.

Persons Leading Sedentary Lives.—That individuals, who may be classified under this head are particularly prone to suffer from alopecia is assumed as a matter of fact. According to the theory, there may be a double reason for this. One is that lack of exercise lessens the quantity of air needed by the system for the purpose of oxygenating the blood, and in consequence lessens the expansion of the chest during respiration. The other is that the head-bent-forward posture, so often assumed by persons of this class when working over desks, causes the scaleni muscles (those three muscular strips that pass down on either side of the neck from the cervical vertebræ to the two upper ribs, and in quiet respiration elevate the upper part of the thorax) to become relaxed to such a degree that muscular contraction in them, sufficient to elevate the ribs when the head is erect, is wasted to a greater or less extent in taking up slack. On account of this there is a constant tendency for individuals of this group to lose whatever superior costal breathing they may have started with and come to employ more and more some other type of respiration.

The Aged.—That alopecia is common among the aged of both sexes is a statement that calls for no proof. The cause for this condition has usually been ascribed to senile changes in the hair itself. The theory we are presenting, however, offers a different explanation of this phenomenon. At the outset attention is called to the fact that the influence of dress, which in adult life has so much to do in separating the types of breathing employed by the two sexes, is in age often eliminated.

In "Gray's Anatomy" we find these words in a description of the articulations of the cartilages of the ribs with the sternum: "After middle life, the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum."

This means that as age comes on, the exertion necessary to carry on the costal type of breathing is constantly becoming greater, and this at a period of life when the muscles are constantly growing weaker. And, in consequence of these conditions, that the respiration, if not already of the abdominal variety, is urged in the direction of this type by influences which are ever becoming more and more potent.

On account of the greater range of motion of the ribs in the female, and also on account of the influence of a lifelong habit of costal breathing, women in age should lose the costal mode of breathing more seldom and more slowly than do men; or, in other words, should suffer more rarely from alopecia. Observation would seem to show that this is the case.

Individuals in General.—In concluding this portion of my paper I may state that a personal observation, extending over a period of ten years and applied to thousands of cases, has never failed to give me ocular proof of the existence or non-existence of superior costal breathing, according as the individual under observation was or was not free from the form of alopecia under consideration.

Experiments Based Upon the Theory and Applied to Various Animals.—The plan here was to keep respired air in the presence of warmth and moisture long enough for decomposition of its organic matter to occur, then to inject the substance resulting from this decomposition into the blood of animals and to note the results. These experiments were begun in

April, 1900, in the Bacteriological Laboratory of the Detroit College of Medicine and were carried out in the following manner:

A middle-aged man, who had long suffered from alopecia, was placed in a pneumatic cabinet and three inches of a vacuum established about him. As he breathed deeply under the influence of this force enough of his expired air was directed into a collapsed rubber bag to distend it. The capacity of the bag used was one gallon and the air was kept from escaping from it by a clamp applied to the rubber tube that formed its nozzle.

Next a half-gallon bottle or flask, previously made sterile, was filled with warm distilled water and closed with a rubber stopper, through which passed two glass tubes in ordinary wash-bottle fashion. The rubber tube of the bag already described was then connected to the shorter of these glass tubes, the clamp closing it was loosened, and by pressure respired air was forced into the flask until the surface of the distilled water had been lowered to within two inches of the bottom (FIG. 1).

As soon as this was accomplished the bag was disconnected from the flask, the wash-bottle stopper was carefully removed and another, also of rubber and with two glass tubes passing through it, was put in its place. The glass tubes of this second stopper were so arranged that inside the flask one reached just through the stopper, while the other extended down some distance and then, at an angle of 45 degrees, passed to near the side of the flask. The former was designed to afford an exit to the liquid when the bottle was tipped up and the latter to allow air to enter as the water flowed out.

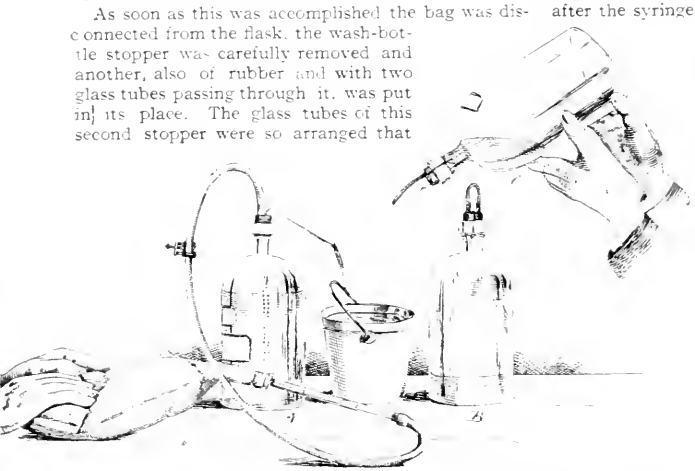

FIG. 1.—Apparatus Used in Making the Experiments. A, Transferring respired air from rubber bag to flask. B, Flask ready to be placed in the incubator. C, Extracting liquid from the flask.

Outside the flask both these tubes reached a short distance above the stopper and were drawn out so nearly to a point that only a small opening was left at the end of each. Finally these openings were closed by a single piece of rubber tubing drawn over the ends so as to form a loop.

By this arrangement it was possible to get water from the flask and at the same time let air flow in so as to afford a vent by simply slipping off the rubber tubing from the shorter of the glass tubes and decanting (FIG. 1).

The flask thus stoppered, with its contents of respired air and distilled water, was placed in an incubator the interior of which was kept at temperature of 98.6° F.

When the flask was placed in the incubator the respired air within, both as to condition and surroundings, was very similar to the same air when chambered in the lungs. Moreover, after it had been in the incubator some hours this similarity was made more marked by the fact that drops of water gathered upon the inner surface of the flask to such an extent that the air within was completely surrounded by a wet surface.

On April 30, 1900, after the flask had been in the incubator ten days, the first injections were made. The animals used were a medium-sized fox terrier dog and a large hen. In the case of the dog the injections were made through the loose skin between the shoulders and in the hen at various points over the abdomen.

The injections were made in the following manner: The flask containing the respired air and water was taken from the incubator, agitated sharply for a few moments so as to entangle in the water any substance that might be in the air, the rubber tubing was slipped off the straight glass tube in the stopper and some of the liquid was poured out into a small-mouthed salt-bottle which had been kept warm in the incubator.

From this bottle an ordinary serum syringe (previously warmed) with a capacity of 5 c. c. (1¼ drachm) was charged and the bottle tightly stoppered. The dog received the first injection and the hen the second after the syringe had been recharged from the liquid remaining in the bottle. These injections were made once daily.

By May 13, 1900, after fourteen injections had been made, a strip of bare skin, about the size of the middle finger, had appeared along the center of the posterior part of the abdomen of the dog, and one the size of the whole hand, over the same part of the hen. By June 1, after thirty-two injections, these patches had extended forward to the breast, in both animals, and also some distance upon the sides. On June 20, after fifty-two injections, the whole abdomen of each animal was bare, and irregular areas of uncovered skin extended upon the sides. These were symmetrically placed on the two sides of the same animal. No further injections were made on these animals after June 20.

During the time they were receiving the injections the animals showed no signs of disturbed health. The dog occupied a large box-stall, and ate his food and played about in a natural manner. The hen had a large furnace room in which to roam about, and besides eating and acting as hens ordinarily do, laid, on an average, two eggs in three days during the whole time. In her case, as in that of the dog, the weight remained unchanged. In both cases the only change apparent in the uncovered skin was an increased dryness.

A constant supply of injecting liquid was kept on hand by charging a new flask, in the manner already described and placing it in the incubator, when it was judged the supply on hand was within ten or twelve days of exhaustion. A flask lasted, on an average, sixteen days. Both the dog and the hen recovered their protective coats after the injections were stopped, but did so rather slowly. The dog regained his first. On July 25, more than a month after the last injection, the hen still had a patch over the abdomen, corresponding to the part first denuded, where a stubble, like shoe-pegs sticking through the skin, represented what in time would become feathers.

After June 20, 1900, no further experimentation was undertaken until the following fall. During the intervening time, the writer had frequently to hear from his medical friends expressions like the following: "Suppose injections, of the kind you

mention, do cause hair and feathers to disappear? What does that prove? Probably continuous daily injections of almost any substance would cause disturbance enough in the nutrition or nervous system of the animal to make hair or feathers fall out.

ately deep inspiration [illegible] few moments, so as to allow [illegible] lungs to become charged with [illegible] material, and then, by forced expiration [illegible] with respired air as possible into the [illegible] rubber bag

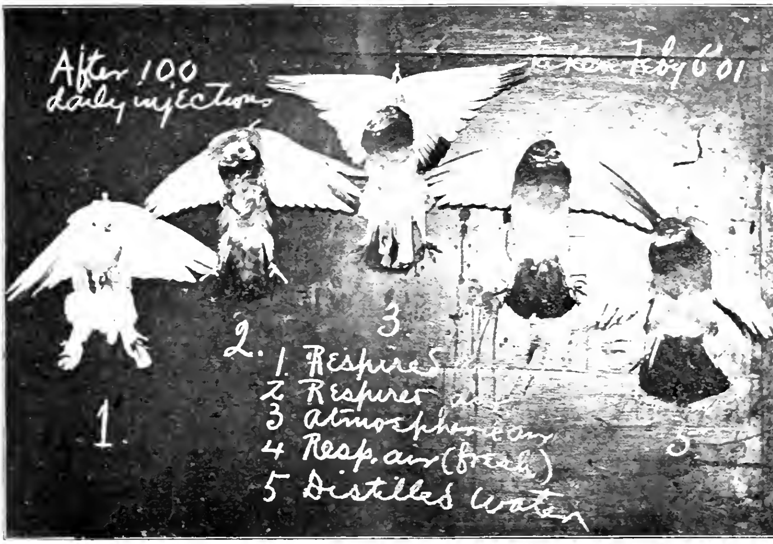

FIG. 2.—Photograph of Pigeons after One Hundred Daily Injections Had Been Given. No. [illegible] liquid from the flask containing respired air from a man not suffering with alopecia. No. 2 received liquid from the flask containing [illegible] from a man suffering with alopecia. No. 3 received liquid from the flask containing atmospheric [illegible]. No. 4 [illegible] liquid from the flask containing freshly expired air. No. 5 received distilled water. Nos. 1 and 2 are the [illegible] ones affected. The breast feathers cover up considerable of the uncovered space.

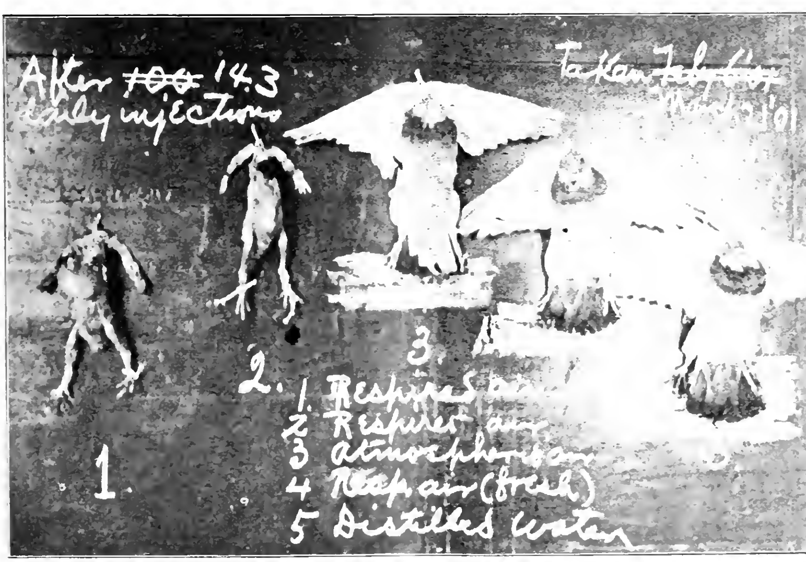
To meet these and other objections, the following experiments were undertaken. On October 20, 1900, a flask was charged with respired air from the lungs of a man not affected with alopecia. This was accomplished by having the man draw a moderately deep inspiration [illegible] before referred to. Usually three such expirations, repeated at intervals of a few minutes, were sufficient to fill the bag. The flask containing this air was labeled No. 1. Another flask was charged with respired air from the lungs of a man affected with



F[illegible]—Photograph of Pigeons after One Hu[illegible] Daily Injections Had Been [illegible]. No. [illegible] of feathers in Nos. 1 and 2 and the uniaffected [illegible] [illegible] proceeding [illegible]

alopecia. The pneumatic cabinet was used in this case. This flask was labeled No. 2. Another flask was charged with atmospheric air. This was labeled No. 3. All these were placed in an incubator as before. Besides these liquids in two other flasks were prepared at the time of use.

The animals used in this series consisted of one fox-terrier dog, five full-grown hens, and five full-grown pigeons. The dog received daily injections

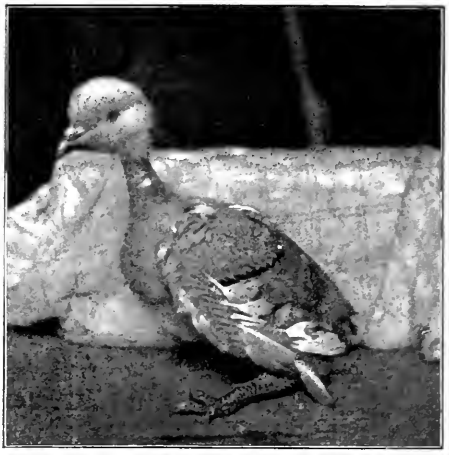


Fig. 4.—Pigeon No. 1 after One Hundred and Forty-three Injections Had Been Given.

from flask No. 1, which contained respired air from a man not affected with alopecia. The results from these injections compared with those of the previous experiment, when respired air from a man with alopecia was used, were identical. The hair disappeared first from the posterior part of the abdomen, and the uncovered area thus starting, increased gradually by extension outward and forward until the whole of the abdomen and sides were bare. After one hundred injections, work on the dog was stopped, and in four or five weeks new hair covered the region that had been affected. So much for the dogs.

The hens and pigeons formed two series treated exactly alike so that a description of one will answer for both. It is necessary only to say, that the effects in the hens, while corresponding in character with those that occurred in the pigeons, were developed more slowly and to a lesser degree, a condition ascribed to the fact that the quantity of liquid injected into the hens was smaller in proportion to body-weight than that given to the pigeons.

The injections were begun on October 29, 1900. Each animal received daily five c. c. (1¼ drachm) of the liquid. Pigeon No. 1 received liquid from flask No. 1, which contained respired air from a man without alopecia. Pigeon No. 2 received liquid from flask No. 2, which contained respired air from a man with alopecia. Pigeon No. 3 received liquid from flask No. 3, which contained atmospheric air. Pigeon No. 4 received liquid from flask No. 4, which contained freshly respired air, that is air, the same as No. 1 except that no time was given for decomposition to occur, and pigeon No. 5 received simply distilled water. The hens received the same substances in the same amounts and in the same order as the pigeons.

The injections proceeded exactly as in the first experiments. By February 6, 1901, after one hundred injections, pigeons Nos. 1 and 2, showed patches upon the abdomen that were bare (see Fig. 2). In the illustration, the long breast feathers cover a large part of the denuded surfaces. The other pigeons were unaffected. After February 6, the quantity of fluid injected daily into each animal was increased from five c. c. (1¼ drachm) to ten c. c. (2½ drachms). On March 21, 1901, after one hundred and forty-three daily injections, pigeons Nos. 1 and 2 had lost completely their protective covering. (See Figs. 3 and 4, which were taken on the same day.) The other pigeons were still unaffected.

In Fig. 3, pigeon No. 2, is dead. On the preceding day, during an altercation with No. 1, he fell or was thrown into a pan of cold water and so chilled that, when found some time later, he was cold and exhausted, and he died soon after. This unfortunate occurence points out the lack of wisdom displayed in keeping these two birds in the same cage.

After March 21 no more injections were given. By April 10, twenty days after receiving the last injection, pigeon No. 1 had regained feathers of about one-third their normal length upon wings, tail, and shoulders. (Fig. 5.)

By May 10, fifty days after the last injection, pigeon No. 1 had regained a coat of feathers normal everywhere, except about the neck, where the skin was still visible when the head was extended. Even here, however, feathers were beginning to grow. (Fig. 6.)

Beyond the accident to pigeon No. 2, there was no interference with the work on account of impaired health of any of the animals. A peculiar circumstance in connection with pigeons Nos. 1 and 2 was the difference in the condition of their skins after the feathers had disappeared. The skin of No. 1 kept soft and pliable and was covered with a white branny desquamation that whitened anything with which it came in contact. The skin of No. 2, on the contrary, was of a bluish color, tightly adherent to the tissues beneath and perfectly free from des-

Fig. 5.—Pigeon No. 1 Twenty Days after the Injections Were Stopped.

quamation. In the hens the only change in the skin was an increased dryness.

Another peculiar circumstance, in connection with the animals that lost their coats, was that the skin appendages about the heads were more resistant to the action of the substance injected than those of other parts of the body. Attention is called to the fact also that in every one of the two dogs, three hens, and

two pigeons that lost their protective coverings, the tissues at the posterior part of the abdomen were the first to be affected, although the injections were made in regions of the body widely different.

The results of the experiments just described show that when respired air from the human lungs is kept chambered in the presence of warmth and moisture long enough for decomposition of its organic matter to take place, there is developed a substance which, when introduced into the blood of certain animals, exerts a selective poisonous action upon the hair, or tissues analogous to hair with which such animals may be endowed, and that beyond this, so far as careful observation can determine, it produces no effect whatever.

Furthermore, the same experiments would seem to show that this peculiar effect cannot be expected to pertain to any substance other than the one mentioned above.

Trichotoxicon.—With the existence and action of the substance under consideration demonstrated, the need of a word, to take the place of a phrase or sentence, in making reference to the substance itself, is apparent. To meet this want, the writer presents Trichotoxicon from the Greek θρίξ, hair, and τοξικον, poison.

Fig. 6.—Pigeon No. 1 Fifty Days after the Injections Were Stopped.

Conclusions.—If trichotoxicon is developed when respired air is chambered in the presence of warmth and moisture outside the lungs, will the same substance be developed when respired air is chambered, with the same surroundings, inside the lungs? It certainly is difficult to think of any reason why it should not.

And again, if trichotoxicon, circulating in the blood current of a lower animal, is bound to exert a specific action upon certain tissues of that animal, is it proof that the same substance, introduced into the blood of a human being, will exert a like influence upon the same tissues, or tissues of an analogous nature, of the human being? While proof seems to be too strong a word to use in this connection, it is not too much to say that there is a great probability that it will.

From a consideration of what has been written above, it seems to the writer not unreasonable to conclude that alopecia, of the type under consideration, is caused by an auto-infection in which trichotoxicon is taken up by the blood from the air-cells of the lungs, where it has been elaborated during decomposition of organic matter normally present in respired air.

550 Jefferson Avenue.

THE FUTURE TREATMENT OF HAY-FEVER.*

By H. Holbrook Curtis, M. D.
New York.

On June 7, 1900, I read a paper[1] entitled "The Immunizing Cure of Hay-Fever" before the American Medical Association at Atlantic City. In this paper I gave an account of experiments which for two years I had been making of internal and hypodermic exhibition of watery extracts of flowers. A résumé of what I said at the June meeting is as follows:

Some two years ago I reported to the Section on Laryngology of the New York Academy of Medicine the results of some experiments that had been made on a patient who, from childhood, had suffered from violent attacks of neurotic coryza, with most severe constitutional complications during the paroxysm. These attacks, simulating the most severe type of an attack of hay-fever, completely prostrated the patient, and usually lasted for about two weeks. The patient, who was an unmarried woman of thirty-five, frequently presented this picture—the finger nails were cyanosed, the extremities were cold, and a state of collapse supervened which required the most vigorous measures to sustain life. These attacks were brought about by an exposure to the perfume of flowers; and so susceptible was she to these odors, that to pass a florist's shop in the street would be sufficient to produce a paroxysm. It was on this patient, who was from one of the best known families of St. Louis, that I determined to try the effect of immunization, by giving internally and hypodermically the watery extract of certain flowers and their pollen. I commenced by giving the sterilized infusion of roses, and after two weeks found that the patient could tolerate that flower in her bedroom. I then tried the violet and lily-of-the-valley, and was equally successful with each flower. After I had immunized her to three flowers, it was found that adding others to the bouquet always kept at her bedside, did not produce any bad effect; and since then there has been no recurrence of the paroxysms that heretofore rendered her life unendurable. This patient, however, was of so pronounced a neurasthenic type—she was also tuberculous—that I made a very guarded report of the case before the Laryngological Section of the Academy at that time, preferring to wait for more experience with other cases before communicating further on the subject.

Another patient once told me that it was impossible for her to go into the ipecac department of a drug house, where she was employed, without getting a violent "crying cold with asthma," and that when she worked in ipecac, she had to take some tincture of syrup in drop doses for several days before she came in contact with the drug—a precaution which she found always prevented an attack. This young lady informed me that a friend of hers was likewise affected and also benefited by the same precaution. It was the remembrance of this case that originally suggested to me the possibility of an immunizing treatment for hay-fever. A point of especial importance is the curious fact that not only is immunity from attack secured by this mode of treatment, but also after the onset of the pollen or flower fever, and the paroxysm is at its height, the attack is at once lessened and often controlled by the exhibition of the causative drug. I have found this to be the case with golden rod and lily-of-the-valley and also with ragweed corasthma. A Philadelphia physician, who is affected with a violent coryza by the odor of salicylic

*Read before the American Laryngological, Rhinological, and Otological Society, May 25, 1901.

[1] *Medical News*, July 7, 1900.

acid, has recently told me that this disturbance does not occur while he is taking the salicylate of sodium.

The experiences narrated above prompted me last summer to obtain through a drug firm the services of a botanist to secure the flowers and pollen of enough ragweed to make an experiment on a large scale this year on so-called hay-fever, and to determine whether the hypothetical deductions from the experiments I have already conducted are truly as important as I believe them to be. The tincture and the fluid extract are the solutions most available. In my recent experiments I have discontinued the use of hypodermic medication.

The drugs were delivered to me so late in August of last year that the preventive treatment could not be carried out, but in no case of the eight or ten on which I tried the treatment at the commencement of the attack, was there anything but remarkable results even when the enemy had been in full control for two weeks.

Permit me to append a letter from a Brooklyn clergyman, which is a good sample of the general estimation in which the drug is held by some of the worst cases on record:

GRACE CHURCH, UTICA, N. Y.,
December 12, 1899.

MY DEAR DR. CURTIS: Before I left Brooklyn, I wanted to write and tell you how deeply I am indebted to you for the relief which you gave me from hay-fever during the past summer and autumn, but the rush of moving prevented my doing so. However, you must listen to my refrain, and it may interest you.

In August, 1889, I had my first attack of hay-fever, when I was living in Wethersfield, Conn., from which place I removed to Brooklyn at the close of the month just mentioned. Regularly, every year since, on August 19th, except in 1894, when it came on August 21st, the hay-fever appeared. In three days, my eyes would be so inflamed and bloodshot that a few minutes with the newspaper was as much reading as I could do; my nose became swollen, and the edges of the nostrils had to be rubbed with salve after the paroxysms of sneezing to prevent them from cracking open. At least one-half of the time I could not breathe through either nostril, and panted with open mouth like a dog; in bed at night I had to prop myself up with pillows to catch any sleep at all; I had no appetite; no anything. This condition would last into October, taper off in November, gradually disappearing after the arrival of the killing frosts. My attack this year had been running several days before I received your medicine, and I was astonished at the abatement of the enemy in forty-eight hours. You know the rest of the story—good appetite, sleep at night, and only enough of a touch of hay-fever for me to know that I was prone to the attack of the fiend.

Perhaps you will now understand why I consider myself to be Most gratefully and sincerely yours

B———.

In the title of this paper, hay fever is used in its popular sense, but the malady to which the treatment I have suggested applies is ragweed corasthma. I have several cases on record of goldenrod and lily-of-the-valley corasthma, which have been cured by solidago odora and convallaria majalis, respectively, in three or four days; but, while these are interesting as contributive evidence, the old enemy, ragweed, is the recognized king of pollens, whose term of office begins August 12th to 20th in these latitudes, and whose cruel reign is only ended by the first frost.

If my theory be correct, that this "rhinitis vasomotoria periodica" or "corasthma ambrosiæ" may be prevented by giving from two to ten drops of the tincture or fluid extract of ambrosia artemisiefolia t. i. d. in water, during the two weeks preceding the paroxysm, I shall consider that I have heralded what I believe to be a great discovery, with becoming modesty. If, on the other hand, the results I have obtained are not verified by others, I may only say that greater men and more scientific observers have been misled by initial results that time did not substantiate. I should be pleased, however, to give to any physician who will conscientiously aid me in investigating the subject such directions that he may experiment for himself upon severe cases, in order that a collection of reports from disinterested physicians in widely separated localities may be of benefit to the cause of scientific research.

In August, 1900, at my suggestion, the fluid extract of ragweed was combined with aromatics in order to disguise its unpleasant taste and make it more palatable to the patient. With every bottle sent out in reply to inquiries from the profession, a blank, which read as follows, was enclosed:

LIQUOR AMBROSIA.

FOR THE PREVENTION OF HAY FEVER.

This preparation is used to immunize those cases which, in these latitudes, are affected about the 15th to the 20th of August.

Cocaine must not be employed as an adjunct.

As this treatment, while affording extraordinary relief to the few cases upon whom it has been tried, is still in the experimental stage, the physician who uses this bottle of medicine will confer a favor by returning this blank, properly filled out

Patient (male or female)?
Age?
How many previous attacks?
Attacks generally commenced?
Attacks generally ended?
Was asthma present?
Was nose occluded during attack?
Was nose perfectly free before attack?
Has the patient any intercurrent disease?
Does patient use alcoholic beverages?
Does patient smoke excessively?
Do other flowers than ragweed cause attacks?
Did patient's father or mother have hay fever?
Do patient's brothers or sisters suffer from the malady?

On October 3d, the following letter was sent to those to whom the medicine had been forwarded:

DEAR SIR: The season is now so far advanced that you may be able to tell with some accuracy whether or not the "Liquor Ambrosia" has been of any use in your case of hay fever.

Kindly let me know what your experience with this remedy has been. Respectfully, etc.

The first thirty-four consecutive replies received to this letter were sufficiently satisfactory to warrant the manufacture of several thousand bottles for the continuation of the experiment another year (eighteen told of complete recoveries, four of considerable improvement, while twelve were negative). In order to get an idea of the difficulties encountered in making a fair estimate as to the value of a new remedy, I reproduce a few of the responses taken at random:

SPRINGFIELD, VT.

DEAR DOCTOR: Worked like magic. Patient greatly relieved in forty-eight hours and cured in a week. Even more brilliant result in another case. — —, M.D.

ST. CLOUD, MINN.

DEAR DOCTOR: In reply to your letter, will say "Liquor Ambrosia" was of great use to me. It practically cured me. If I had taken it before the attack became seated on me, I feel sure it would have prevented it entirely. I intend to lay in a stock next year, and feel sure it will prove entirely effective.

DEAR DOCTOR: The result obtained from the use of "Liquor Ambrosia" has been a success. Three bottles have been used, and the suffering at no time has been severe. The patient thus expressed himself: "The medicine has done all that could be expected."

———, M.D.

NEW YORK.

DEAR DOCTOR. I beg leave to acknowledge receipt of the bottle of "Liquor Ambrosia" which you had the kindness to send me. I have been taking it according to directions over a period of four days, since which time I have not had any trouble from my hay-fever, and during the last three days have not sneezed at all.

I beg to thank you for your thoughtfulness in supplying this remedy, and with kind regards, I remain.

———.

SPRING LAKE, N. J.

DEAR DOCTOR. In reply to your letter of October 3, I would say that I believe my son said he did not experience any particular relief from the medicine.

———

WASHINGTON, D. C.

DEAR DOCTOR: My experience with the "Liquor Ambrosia" has been very satisfactory. I am about sending notes of my own case, but I do not wish my name used publicly, although privately I am speaking freely in its favor. I know of three cases where it seemed to greatly ameliorate the symptoms, although not taken until the middle of the attack. I think you will be quite justified in preparing it freely for use in the next season. ———, M. D.

LOCKPORT, N. Y.

DEAR DOCTOR,] Replying to yours of the 3d, just received, I am pleased to say that my wife and myself used the "Liquor Ambrosia" during the attack of hay fever, and that it appeared to afford some relief—at least I did not suffer as much this year as during previous years. We used three bottles and then gave it up—feeling that we did not commence its use early enough for it to act as a preventive. The attack was well on its way when we commenced its use. We feel now we will try it next year a few weeks before the season. ———.

BROCKTON, MASS.

DEAR DOCTOR: Replying to your courteous note of inquiry of the 3d inst., regarding the results of the "Liquor Ambrosia," in my hand, I can only say that my observation with the drug is confined entirely to its effect in my own person. Commenced August 6th taking the Liquor in ℥i doses, t.i.d. and continued it with gradually increasing doses to ℥ii t.i.d. till September 6th. I regret to say I observed no appreciable effect; possibly the onset of my attack of hay fever was a little later in coming on; otherwise no change. ———, M.D.

BUFFALO, N. Y.

DEAR DOCTOR: Relief derived from the remedy has been most satisfactory. I increased dose during worst days at end of August to two or three teaspoonfuls, as necessary to fight off the attacks. I remained in the farming section and played golf in the midst of all kinds of weeds, with entire comfort. Sometimes, in the worst days, I took as many as 15 teaspoonfuls of the Ambrosia in 24 hours.

LA CRESCENTA, WIS.

DEAR DOCTOR: Your letter to Mr. ——— of this place, of October 3d, has been handed to me for a reply; since the case of hay-fever in his family was under my observation, and being a sufferer, I took the remedy a short time.

In neither case were the results at all satisfactory. Possibly we began treatment too late in the season, the attack having begun. In both cases, considerable stomach disturbance even from minimum doses caused, after a few days' use, much inconvenience. I was much disappointed, but will give it another trial on some other cases next year. Much of our supply remains in my hands. Does it keep indefinitely?

Regretting I cannot report more favorably, I am, etc., ———, M.D.

UNION CITY, IND.

DEAR DOCTOR: I secured the medicine for my own use, after receiving the reprint of your article. You will see by enclosed blank that I have experienced probably twenty attacks. Have tried out most lines of treatment promulgated by the profession, but with very different results. Attack commenced this year on the 8th of August. Received the Ambrosia on the 22d or 23d, and commenced taking it. Attack was an unusually severe one, with more of less asthma every night. Improvement was marked from the first day, and continued with such gratifying results that, at the end of one week, I discontinued the Ambrosia, and did not take it again during the season, having continued practically free of the disease. I took about one-half of one bottle during the week. After the first day of treatment, I had no recurrence of asthma; after two of three days could breathe freely through the nose, the conjunctivitis disappeared, and I was practically well, although I had a slight coryza, with some sneezing during balance of the season.

Let me suggest that Ambrosia in tablet form would be a desideratum.

With regards, I am, yours very respectfully,

———, M. D.

From a careful estimate from all sources of information, and from my own personal experiences, which may cover about one hundred cases, I have concluded that cases which are dependent entirely upon ragweed as an exciting cause, may become immunized in about sixty per cent. of the number treated. When there exists a mixed infection, and when the cases show a preponderance of asthmatic symptoms, a nasal spray of suprarenal extract may with benefit be employed. An internal exhibition of the suprarenal products is also beneficial to the dyspnœa as well as to the œdematous condition of the nasal mucous membrane.

Last year's work has demonstrated that a preparation of ragweed is in a majority of cases an adjunct of very great value in the treatment of hay fever, and it seems reasonable to suppose that perhaps a tincture of goldenrod or some other plant may be found efficacious in those cases in which the ragweed seems to have no appreciable effect. Exactly how great a palliative this treatment will prove will of necessity take two or three years' investigation to determine, as it is impossible to get a layman to take sufficient interest in the subject to send a proper analysis of his case, and to overcome the timidity of the professional man in introducing any remedy unless he feels that his name and reputation will not suffer thereby.

I can therefore thus far only report a most satisfactory progress with the possibility of a very favorable outcome in regard to the immunizing treatment of hay fever.

118 MADISON AVENUE.

Epiploitis Mistaken for Strangulated Hernia.—A. L. Peyroux reports a case in which a painful, hard, tense, irreducible tumor of the scrotal pubic region apparent after an accident on horseback. It was accompanied by vomiting, constipation, and a bad general condition, with a feeble and slow pulse (45 a minute). The diagnosis of strangulated hernia was made, and operation was begun, but no hernia was found. Epiplocele was present and was radically cured. The author justifies the error made in the diagnosis by the fact that all the symptoms given were those of hernia. Moreover the treatment was perfectly correct for the condition found.—*Archives Provinciales de Chirurgie.*

Pathogeny of Nasal Hydrorrhœa in Spasmodic Coryza.—Upon microscopical examination of the tissues in this condition, Brindel finds an accumulation of round cells in the neighborhood of the epithelium and an epithelial desquamation corresponding to the crisis of the attack. There are a considerable multiplication of the blood vessels and very marked dilatation of the veins. Extravasations of blood occur in the tissues of the mucosa principally toward its external surface. Hydrorrhœa is to be looked upon, not as a function of secretion, but as a transudation of serum (possibly a little bloody) though the meshes of the connective tissue of the mucosa, a sort of œdema with immediate excretion of extravasated liquid. The exact pathogeny of this vasomotor dilatation is still undetermined.—*Revue Hebdomadaire de Laryngologie, etc.*

THE PRESENT STATUS OF THE CARCINOMA QUESTION.

By N. SENN, M. D., Ph. D., LL. D.

CHICAGO.

PROFESSOR OF SURGERY, RUSH MEDICAL COLLEGE, IN AFFILIATION WITH THE UNIVERSITY OF CHICAGO; SURGEON-IN-CHIEF, ST. JOSEPH'S HOSPITAL; ATTENDING SURGEON, PRESBYTERIAN HOSPITAL; PROFESSORIAL LECTURER ON MILITARY SURGERY, UNIVERSITY OF CHICAGO.

Propositions.—1. The most notable contributions to the present status of the carcinoma question are to be found in the investigations which have thrown new light on the origin, growth, segmentation, and manner of local and general dissemination of the carcinoma cell.

2. Carcinoma is a tumor resulting from an atypical proliferation of epithelial cells from a matrix of embryonic cells of congenital or post-natal origin.

3. The law of the legitimate succession of cells holds true in the origin and growth of tumors, both benign and malignant, as well as in the production of normal and inflammatory tissue.

4. As carcinoma always originates from epithelial cells, primary carcinoma in mesoblastic tissue is impossible from a histogenic standpoint, unless a matrix of embryonic epithelial cells has become displaced during the development of the embryo or embryonic epithelial cells have become buried in mesoblastic tissues after birth, by injury or disease.

5. The histology and histogenesis of carcinoma speak against the parasitic origin of this disease.

6. The stroma of carcinoma consists of pre-existing connective tissue fibers and their descendants.

7. Carcinoma cells usually multiply by irregular atypical karyokinesis, and this pathological segmentation is an important indication of malignancy, and as such is of considerable diagnostic value.

8. The progressive extension of a tumor to adjacent tissues and organs, regardless of their anatomical structure, is a strong proof of its carcinomatous character.

9. Regional metastasis in carcinoma takes place exclusively through the lymphatic channels, and the pre-existing lymphatic structures take no active part in the origin and growth of the secondary tumors.

10. General dissemination of carcinoma usually takes place by direct implication of veins in the primary or secondary tumors. Carcinoma cells reach the venous circulation through the formation of an intravenous tumor thrombus, through carcinomatous endophlebitis, or, finally, through perforation of the vein wall by isolated carcinoma cells. Retrograde intravenous extension of carcinoma is due to the transportation against the venous current of minute emboli of carcinoma cells surrounded by a mantle of blood corpuscles which move, step by step, upon the intima. Retrograde extension through the lymphatics may take place in the same manner, but there is very little doubt that it is more frequently the result of carcinomatous endolymphanitis.

11. The increase of carcinoma seemingly shown by some recent statistics is more apparent than real.

12. Heredity is a generally recognized potent predisposing cause of carcinoma.

13. As a rule, carcinoma occurs in persons of advanced age, but occasionally is met with in persons less than twenty-five years of age, and in the latter case the disease is characterized clinically by its great malignancy.

14. Carcinoma seldom follows a single injury, but develops more frequently in consequence of repeated injuries or prolonged continuous irritation.

15. Among the predisposing causes of carcinoma must be enumerated racial, climatic, and topographical influences.

16. Chronic inflammatory products, cicatrices and benign epithelial tumors produce local conditions favorable to the development of carcinoma.

17. The positive results of implantation and inoculation experiments have so far failed in establishing beyond all doubt upon a bacteriological and histological basis, the parasitic theory of carcinoma.

18. A careful study of the experimental researches and bacteriological and histological investigations concerning the etiology of carcinoma does not at the present time warrant us to claim for this disease a parasitic origin.

19. The experience of centuries and the internal use of innumerable remedies have demonstrated that so far carcinoma has not been materially influenced for the better by this method of treatment.

20. Direct medication of carcinomatous tissue by parenchymatous injections has no influence in retarding or arresting its growth, while the injection of sclerogenic substances into the connective tissue around the border of the tumor appears to restrain the local extension of the disease by impairing the blood supply to the parenchyma of the tumor.

21. Local applications of any kind in the treatment of ulcerating carcinoma must be considered at best only in the light of palliative measures.

22. The actual cautery and chemical caustics have only a limited field of usefulness in the treatment of open inoperable carcinoma. They should never be employed in the treatment of closed carcinoma as a substitute for the knife.

23. The treatment of carcinoma by different sera has, without any exceptions, yielded only negative results.

24. The early and radical operative treatment of carcinoma offers the only prospect for permanently eliminating the disease.

25. The permanency of the results of the operative treatment of carcinoma cannot be determined in less than ten years after the operation.

26. A radical operation for carcinoma should never be attempted unless the local conditions and general health of the patient are such as to promise an equivalent of the immediate and remote risks to life and comfort involved in the operation.

27. Taking it for granted that carcinoma is the product of an erratic, planless cell-growth outside of the range of the physiological influences which preside over and regulate normal growth and tissue repair, it appears logical in the search for curative agencies to make experiments and observations with the view of finding a remedy which would destroy the tumor by causing an early and speedy degeneration of its parenchyma, or which would possess the property of converting embryonic into mature epithelial cells, thus converting a carcinoma into a benign epithelioma.

Some Remarks upon Venom and Antivenene.—Joseph McFarland concludes that by the subcutaneous and intravenous injection of unheated crotalus venom it is possible to immunize horses against the chief toxicelement—the nervous poison. The immunity thus afforded is very slightly protective against the irritative poison contained in the venom, and animals whose serum contains even much antivenene may succumb to the local effects of the venom. The development of the immunity is accompanied by the occurrence of large quantities of antivenene in the blood of the immunized animal. The antivenene is fully able to save animals from both crotalus and cobra venoms. The quantity of antivenene in the blood fluctuates according to circumstances, as do other antitoxic serums, and declines as the vital condition of the horse is depressed. The normal endurance of horses to venom varies considerably. The intravenous method of administering the unmodified venom is the best as it is

not attended by sloughing of the tissues. As the immunity does not extend to the irritative poison, and as the protection afforded to animals receiving antivenene is against the venom, not the irritative poison, it is probable that Calmette's method of immunizing animals with modified (heated) venom, which contains more of the irritative substance, saves the animals suffering, and does not endanger their lives.—*Proceedings of the Pathological Society of Philadelphia.*

Experimental Dysentery in Dogs.—H. F. Harris, finding that it was impossible to cultivate the amœba found in dysentery, attempted to cultivate all of the bacteria in the discharges of dysenteric patients, and to determine if these mixed cultures were capable of setting up a dysenteric process. Cultures were therefore made and injected into the intestines of four puppies. There was absolutely no effect produced. It seems therefore unreasonable to conclude that the germ that produced the disease is a bacterium, or at any rate, it seems fairly certain that it cannot be an organism that develops in the culture media ordinarily employed. As the amœba coli was the only other living organism found in the feces that was probably absent from the cultures, it seems logical to suppose that this parasite is the cause of any morbid state that the injection of these discharges may give rise to.—*Proceedings of the Pathological Society of Philadelphia.*

An Eruption Resembling Pemphigus Vegetans in an Infant.—E. A. Fischkin reports the case of an infant five months old, presenting an eruption difficult of diagnosis. Syphilis had to be excluded, nor could mycotic disease be admitted. The fact that there had been preceding emaciation, that the disease started with a bronchial catarrh, that the first lesion appeared close to the anus, and that the lesions which were on the upper and lower extremities, cheeks, and forehead were cardylunate with a very few blebs, confirmed the diagnosis of pemphigus vegetans. Corrosive sublimate baths and dusting the lesions with a salicylated starch powder, with elixir calisaya as a tonic, produced such rapid improvement in eighteen days that the author now hesitates to call the disease pemphigus vegetans. He still excludes syphilis for good reasons, but inclines to regard the affection as a trichophytosis.—*Pediatrics.*

Insanity in Women from the Gynecological and Obstetrical Point of View.—A. Lapthorn Smith does not believe in the heredity of insanity, but thinks it is sometimes contagious. Often it is due, not to organic disease of the brain, but to functional disorders of the circulation and of the blood. In many women the disorder of the brain's circulation is caused by reflex irritation carried by the sympathetic from the pelvic organs and caused by retroversion of the uterus, cirrhotic ovaries, fibroid tumors, etc. Hundreds of cases are on record of insanity being cured by removal of the cause, the greatest number of mental cures having followed ventrofixation and the shortening of the round ligaments, for the removal of retro-displacements, while many others have followed the ablation of fibroids, cirrhotic ovaries, the repair of lacerated cervices, and even curetting. If anything is done it must be done thoroughly, as several cases have been reported in which no benefit resulted until a second and more complete operation was performed.—*St. Louis Medical Review.*

New Method of Suture for the Anastomosis of the Cut Vas Deferens or Ureter.—Antonio Ferraro in his experiments on animals, cuts the vas deferens, and into one of the stumps introduces a sewing needle, or slender stiletto, and at a certain determined distance from the extremity of the stump makes a transverse incision of half the circumference of the duct. From the middle point of this incision he makes a longitudinal one which reaches to the extremity of the stump. The same procedure is repeated on the other cut portion of the duct, and there are now two quadrangular flaps, which being placed with their mucous surfaces in contact will be found in perfect coaptation, while the lumen of the duct instead of being constricted is increased. The same procedure can be applied to the ureter when necessary.—*La Riforma Medica.*

A Practitioner's Treatment of Inflammatory and Ulcerative Conditions of the Larynx.—H. Beaman Douglass says the most successful method of treating cases of acute laryngitis, when it is important to recover the voice in a short time, consists in the use of six remedies: (1) An absolutely even temperature, which means that the patient must remain in the same room, which room must be well ventilated and kept at a constant temperature of 67° to 70° F., day and night. (2) Bodily massage given twice a day. (3) The bowels should be moved rather freely. (4) The voice should be rested. (5) Tartar emetic internally, $\frac{1}{20}$ grain every hour until nausea appears, or until there is a marked exudation of mucus from the larynx. (6) Applications of sprays of a 6 per cent. solution of suprarenal extract locally into the larynx. The author gives detailed directions for many forms of treatment, but the above he considers most useful in the worst cases of acute catarrhal laryngitis.—*The Post-Graduate.*

Primary Syphiloma of the Conjunctiva.—Carlo Fruginele states that this condition is less rare than usually supposed. It may occur in either sex, in any profession, and usually in persons between twenty and thirty years of age. Its most frequent seat is towards the inner canthus of the eye, and it is usually due to kissing on the eye. It is preceded and followed by a catarrhal conjunctivitis, and characterized by an ulceration of varying size. Its diagnosis is easy, although it might be mistaken for gumma, or for epithelioma. The prognosis is good for the conjunctival lesion, but not for general infection. Treatment is general.—*Giornale della Associazione Napoletana di Medici e Naturalisti.*

Stammering.—C. Biaggi holds that stammering is a degeneration of speech, resulting from an arrest of development in the powers of co-ordination of the movements essential to speech. Children who stammer usually exhibit other signs of nervous taint. The remedy consists in gradual, patient training of the individual muscular movements producing speech. By degrees they can be co-ordinated and combined. At the same time the pupil should be taught to control the bodily contortions and facial grimaces which are so apt to accompany their efforts to speak. In this systematic method of exercise, comparable to the patient and constantly repeated efforts necessary for the learning of the scales and exercises on the piano, the child will gradually acquire control of his speech instrument and become perfect in its technique.—*La Tribuna Medica.*

Have We a Continued Fever Which is Neither Malarial nor Typhoid?—T. J. Happel of Tennessee refers to a group of cases presenting the regular symptoms of either typhoid fever or malaria in which the Widal test and the microscope yield respectively negative results. The features of this unnamed fever are as follows: Malaise may or may not precede the onset. The fever may appear at any time of year. The initial chill may be slight or severe. The fever curve shows two or three ascents every twenty-four hours. As the case goes on to recovery there is a gradual dropping out of these rises until only one may remain. During defervescence

there may be profuse sweats. There is no delirium no matter what the temperature may be. The tongue is moist and but little coated. The patient does not feel very sick. Constipation is the rule. Rash is absent. There are no rose-colored spots. The pulse and temperature present a marked peculiarity. There is frequently an inverse ratio existing between the two, but the rule is that, except in rare cases, the pulse varies but little from normal, rarely (except in cases in which some local lesions can be determined) beating more frequently than 100 even when the temperature rises to 104° or 105° F. Many of these cases linger along from three to eight weeks of sickness with the pulse not above 84. The only time that we find any normal relation between pulse and temperature is in the last week, when the fever becomes intermittent. In a few cases this relation of pulse to temperature is reversed, and a frequent pulse is found with a low temperature. There is no typhoid facies. There is neither the complete loss of appetite seen in typhoid fever nor the nausea and anorexia of malaria. There are no gurglings in the iliac fossa, no perceptible changes in the liver or spleen, and no symptoms in the respiratory tract. One attack does not prevent another. Between this fever and malarial fevers, pure and simple, there is this prominent diagnostic symptom: In malarial fevers patients are sick from the time of the initial chill or rigor, whilst in this, after the first chill or rigor has passed off and the fever has risen and been reduced in any way, the condition of euphoria, already mentioned, develops, and it is hard to satisfy the patient that he is sick or explain to him why he cannot be at once restored to health. Quinine does not cure this fever.—*Memphis Medical Monthly.*

Serum Diagnosis in Typhoid Fever.—G. B. Mariotti Bianchi concludes that the Widal reaction is always positive in typhoid cases, providing that if it fail at first we repeat the test at a later stage. In some fatal and altogether exceptional cases it is absent throughout the disease. The solution adapted to clinical use is 1:40, at which strength we may be certain of not finding the reaction in other diseases, whereas with a 1:20 for instance, we might obtain agglutination, though rarely, in some other cases of infection. As a rule the agglutinating power of serum appears during the second week. For an early diagnosis Newfeld's method would be the better. The rapidity of appearance of the agglutinating power has no absolute prognostic value, but as a rule, by the use of the 1:40 serum, in cultures of equal sensitiveness to specific serums, the more rapidly the agglutination occurs, the better the prognosis.—*Giornale Medico del Regio Esercito.*

Krymotherapy for Anorexia.—Ilzol Haug describes a new method of stimulating the appetite in wasting diseases to which he gives the above name and for which he claims great efficacy. It consists in filling bags of sailcloth with carbonic acid snow (which is produced when a cylinder containing the liquified gas is opened, the rapid evaporation of the first portions of gas producing so great a degree of cold that the succeeding fluid is transformed into a solid white mass, which retains this state for a considerable length of time), and applying them to the gastric region for about a half hour the same length of time before meals. The surface temperature can in this way be reduced as low as 5° C. but the patients do not experience any unpleasant sensations and after four or five days of this treatment enjoy a remarkable increase of appetite. This is to be explained by the local congestion following the intense ischæmia at first produced, whereby the increased blood supply stimulates oxidation to an unusual degree.—*Klinisch-therapeutische Wochenschrift.*

Eclampsia and the Thyroid Gland.—H. Oliphant Nicholson was led by the observation of various facts to consider that there might be a possible connection between puerperal eclampsia and the thyroid gland. He reports a case of successful treatment of the eclamptic condition with thyroid extract. The theory of its action is given by the author. Practically, in the early stages of the disease, he would give the remedy in five-grain doses night and morning, and after a few days three times a day; when the symptoms of eclampsia have appeared, he would give by hypodermic injection 10 or 15 minims of the liquor thyroidei, to be repeated every hour or two if necessary; or, better yet, ten minims of fresh juice from a sheep's thyroid with an equal quantity of distilled water. Morphine should be used, not less than half a grain for the first injection.—*The Scottish Medical and Surgical Journal.*

Note on the Treatment of the Hair in Typhoid Fever.—H. M. Little has examined into the results of treatment of the hair under different conditions. Sixty-two patients were seen some months after their recovery and the results of treatment noted. Of these thirty-five had their hair cut while in the hospital, and in only seven was subsequent falling of the hair noted. Of these seven, four were cut late. The ultimate result in all was a thicker growth of hair than ever before. In two cases it was thought to be coarser than before. Twenty-seven patients (fifteen women, twelve men), did not have their hair cut, and the hair fell out in all but three. Ten had to have their hair cut later to prevent baldness, seven being women. In seven other cases, not cut, in four the hair was very thin, in two the hair was still falling, and in one the hair, curly before, became thin and straight.—*The Montreal Medical Journal.*

A Case of Failure in the Treatment of Tetanus by Baccelli's Method.—Gilberto Salvioli reports the case of an insane woman, suffering from tetanus due to the infection of self-inflicted wounds. Baccelli recommends the hypodermic injection of 2 to 4 cgm. of carbolic acid every two or three hours until 35–72 cgm. are given daily, it having been found that this substance diminishes the spasms and contractures, acts as an antitoxin and moderates the reflex action of the nerve centres. The writer gave forty-five injections, equivalent to gm. 1.8 of phenic acid in five days, but the patient died. She was in an impoverished organic condition and there had been a month's incubation of the disease, so that she was a poor subject for the testing of the remedy.—*La Riforma Medica.*

Scarlatinoid.—Trammer describes an epidemic of an erythematous disease which in external appearances resembles scarlet fever, but which is clearly distinguished from it by certain characteristics. The exanthem appears first upon the face, that is upon the cheeks, is distinctly papular in character and intensely itchy; it spreads rapidly over the entire body, and disappears in from one to three days. Complications or sequelæ are wanting, so that it is an absolutely benign disease. The affection begins with fever, angina, and coryza and is considered morphologically to resemble scarlet fever. Hence the term scarlatinoid.—*Wiener Medizinische Wochenschrift.*

Notes Upon the Urine of a Newly-Born Infant.—George Carpenter reports the case of a female child whose urine constantly contained a trace of albumin. A large amount of urine was evacuated daily, 18½ ounces the first twenty hours that observations were taken, while for the ten following days the smallest quantity was 17 ounces, the largest 22½. The specific gravity was low, usually 1.001 to 1.002, the highest obtained being 1.005. Casts were absent, and the amount of urea was small, varying between ½ and ¼ grain per fluid ounce. There was no evidence of organic disease, and the infant is now well and thriving.—*The Medical Press and Circular.*

MEDICAL RECORD:

New York, July 13, 1901

THE ARMY MEDICAL SERVICE.

THE fact that the three boards created during the past winter for the examination of candidates for commission in the Medical Corps of the Army have concluded their labors without having been able to fill more than about one-third of the previously existing vacancies in that department, calls attention to the serious condition of affairs in the medical branch of the military service.

This condition is of recent development and is directly attributable to the army reorganization bill, so far as it affects the Medical Department, passed by Congress during its late session, and it was clearly foreseen and pointed out to Congress, at the time the bill was under consideration, by Surgeon-General Sternberg and various medical officers on duty in Washington. It was anticipated by the Committee on Legislation of the American Medical Association, which appeared before the Military Committee of the Senate and urged that the carefully considered recommendations of the Surgeon General —who was naturally better fitted to appreciate the necessities of his own department—rather than the provisions of a bill drawn by an officer of another staff department, should be given favorable consideration. The whole subject was fully gone over in detail, and the plea of ignorance on the part of Congress, with respect to the probable effect of this bill upon the Medical Department, cannot be entertained.

Previous to the passage of the army reorganization bill, the *personnel* of the Medical Department consisted of 1 brigadier-general, 6 colonels, 10 lieutenant-colonels, 50 majors, and 125 assistant surgeons with the rank of captain or first lieutenant. With the rate of promotion existing under this organization, medical officers were assured of reaching the grade of major after about eighteen years of service, were certain of attaining the rank of lieutenant-colonel, and, except in a very few instances, might expect to reach the grade of full colonel before passing upon the retired list. Such promotion ensured a comfortable income, increasing as the medical officer was promoted from grade to grade, until as a colonel his pay proper amounted to $4,500 annually and his allowances represented a money value of about half as much in addition.

The medical officer could thus look forward to the ultimate attainment of such rank as would not only provide sufficient means for the education of his children but would carry with it such retired pay as would enable him to spend the last few years of his life in peace and comfort without the necessity of providing for the "rainy day" which must enter into the calculations of the average physician in civil life.

Under such conditions, competition for commissions in the Medical Corps had been for many years very keen among the young medical men of the country. With a large number of candidates from whom selection could be made, a high degree of professional efficiency could be required; with the result that those who were finally commissioned—selected men from what was probably an originally superior class—could fairly be regarded as representing the better element of the medical profession throughout the country. Statistics for the past decade show that scarcely ten per cent. of candidates were able to attain the extremely high standards fixed by army medical examining boards. Recruited in this manner, it is not surprising that the Medical Corps, though until recently limited in numbers to but 192 men, includes in its *personnel* such widely-known men as Sternberg, Billings, Smart, Gorgas, Reed and others who stand with the leaders of the profession in the advancement of medical science; as well as Hoff, Leonard Wood, and others whose remarkable executive abilities, particularly evident during and since the war with Spain, have brought not only fame to themselves but honor to the corps which they so worthily represented. Men of such qualities are those who are desired in the Army Medical Corps, and experience has demonstrated that, with the inducements in respect to promotion and pay formerly offered, such men could be secured for the military service.

The army reorganization bill, while it increased the Medical Corps by one hundred and twenty-nine men, provided for this increase almost entirely in the lower grades, the Corps being enlarged by the addition of two colonels, two lieutenant-colonels, ten majors, and one hundred and fifteen captains and lieutenants. The number of captains and lieutenants was thus increased from 125 to 240, while that of the senior officers was increased only from 67 to 81; thus practically reducing the chances of promotion to the grade of major and above in the proportion of from one in two to one in three—or increasing the length of service necessary to attain the grade of major from eighteen years to about twenty-seven years. In fact, so few were the places of higher rank provided under this bill, that, with a large number of young medical men of about the same age entering at the same time, many of the new comers could never expect to attain the grade even of major before retirement. The bill worked no hardships to medical officers already in the service, but its evil effects were directed toward that class of young men upon whom the future efficiency of the Medical Department must depend.

This condition of affairs, while grave in itself, was aggravated in the minds of medical officers by the fact that in no other staff department was promotion so reduced by the army reorganization bill, and it was felt that the Medical Corps had been subjected to unfair and humiliating discrimination. In spite of the fact that the Medical Corps is pre-eminently the scientific corps of the army, the law just enacted

graded it for rank, promotion, and pay below every other staff department and special corps of the army, and, with the exception of second lieutenants, graded it below the line. In accordance with the provisions of this law, a medical officer, to obtain a colonelcy, must in the future pass through three times as many files as an officer of the Quartermaster, Subsistence, or Pay Departments, through more than twice as many files as an officer of the Engineer or Ordnance Departments, and more than one and one-half times as many files as an officer of the Signal Corps. The discrimination against medical officers, compared with senior officers of the line, is equally striking; thus officers of the line, having attained the grade of major, have to pass through but four files to obtain the rank of colonel, while the medical officer has to pass through nine such files.

All these facts are fully appreciated by young physicians, several hundreds of whom are now serving with troops as contract surgeons, and they are declining to become candidates for positions offering so little in the line of promotion and future pay. The young man of worth and spirit is repelled, and he who is willing to accept a position offering such few inducements as a life career will scarcely be possessed of more than mediocre attainments. Men of this class, however, are not desired in the Medical Corps of the army and a lowering of the professional requirements for admittance, as they have been fixed for many years, has not as yet occurred—hence the vacancies, more than eighty in number, which exist in the corps at the present time.

The remedy for the above serious and unjust condition of affairs is simple. The service must be made more attractive, so that the same class of good men will make it their life career in the future as have done so in the past. It is a plain business proposition that the efficiency of the Medical Department must depend upon the class of men who enter it, and that the class of men which can be secured will depend upon the emoluments offered. These emoluments under the army reorganization bill are not what they have been in the past; consequently, until this defect is remedied, an equally good class of men will not come up in any number for examination. The health of the army lies at the foundation of its efficiency. Money, time, and labor spent in training, sheltering, and subsisting the soldier are lost unless a sound physical condition enables him to make return for what the State has expended upon him. The Medical Department, which is responsible for the sanitary condition of troops, is thus most important of all the staff departments, and the interests of the service and country require that it be maintained in a high state of efficiency. If the demand for young medical men of high professional attainments is greater than the supply, then the supply must be increased by higher pay, or, by what amounts to the same thing, better chances of promotion. Congress is responsible for the present state of affairs; Congress should remedy it at its next session.

The Medical Corps of the army has done too much for the advancement of medical science to fail of the earnest and active support of the profession of the country in its efforts to maintain its present high standard of efficiency for the future. To the practitioner of medicine outside the army the recent reorganization bill presents features of directly personal importance. As expressed by Dr. Reed, in his President's Address at the recent meeting of the American Medical Association at St. Paul: "When the Congress, by the enactment of a law, degrades, relatively, the status of an important body of medical men, engaged in the public service, it strikes at the status of every physician in the country. It becomes, therefore, the duty of every member of the medical profession . . . . . to resent as personal between himself and every member of the Congress who voted for this law, the action which cast a stigma upon our profession."

INFECTION AND INTOXICATION.

The interesting letter of Dr. Wasdin, in the Medical Record for June 8th, would seem to call for some reply in justification of the views expressed in our editorial in the issue for May 18th. From a knowledge of Dr. Wasdin's previous communications on allied questions, we feel secure in stating that there is no radical difference between us, that which exists being related to matters of terminology or definition. Dr. Wasdin states that "infection can only mean the reception of an organism into some portion of the animal body and its colonization at such point of entrance." This definition is obviously inadequate, inasmuch as the mere presence of micro-organisms can scarcely constitute infection, else most of us would be constantly infected with pneumococci, with colon bacilli, with streptococci, with staphylococci, etc. From the same standpoint, non-pathogenic bacteria would not, without some transformation within themselves or in their host rendering them pathogenic, be capable of giving rise to infection. As a result of the activity of the invading organisms and of the reaction of the invaded organism, certain substances are generated that exercise morbid physiological effects and are responsible for the state of intoxication, as manifested by chill, fever, delirium, headache, etc. It would seem better, therefore, to include as a necessary part of the process of infection an exhibition of the pathogenic properties of the invading organisms, together with the reaction on the part of the invaded organism.

From these preliminary considerations it will be appreciated that the terms infection and intoxication are all-sufficient to designate the fundamental features of most morbid processes. Infection may be local or general, while intoxication is necessarily constitutional. Just as local infection, so also general infection can occur only under certain favoring conditions which we designate comprehensively as susceptibility. The development of infection, local or general, is not dependent upon qualities of the invading or of the invaded organism alone, but upon certain mutual and reciprocal affinities of each. In the present state of knowledge, it seems safe to assume that infections are necessarily specific.

We are still of the opinion that the term bacteræmia is the preferable designation for general infection, rather than sepsis or septicæmia, as the former is distinctive and unambiguous, while the latter is precisely the reverse. Bacteræmia can mean only the presence of bacteria in the blood, with its consequences, while septicæmia means the presence of septic matters in the blood, and septic matters, etiologically, are putrid matters, and therefore essen-

tially toxic. The word, septicæmia, further, is used somewhat loosely to designate infection or intoxication, or even both. An insuperable objection to the use of the term septicæmia to designate the morbid results of the presence of bacteria in the circulation resides in the fact, therefore, that it is both unnecessary and confusing, as it does not imply the presence of bacteria in the blood (as does the term bacteræmia most clearly), and it does imply the existence of a toxic state (for which, as we have said, the term intoxication would seem sufficient).

ALLEGED BRUTAL TREATMENT OF THE INSANE.

A CORONER'S jury, in this city, recently censured, in the strongest terms, a physician and two of the nurses in the Manhattan State Hospital, on Ward's Island, the first for neglect of duty and the latter for inflicting bodily injuries which accelerated, if they did not actually cause, the death of an inmate of that institution. The patient had chronic nephritis and acute mania, but the coroner's physician also found several broken ribs and extensive bruises on the head and chest. The same physician recently found evidences of brutal violence on the body of a patient who had died in the insane ward at Bellevue Hospital. The hospital authorities said the police had clubbed the man before bringing him to the hospital, and this the police very naturally denied, throwing the charge of maltreatment back upon the hospital attendants. In order to prevent such disputes in the future, and incidentally perhaps to save the lives of helpless lunatics, a rule has been made that every patient taken to a city hospital by the police must be submitted to a careful physical examination in the presence of police and hospital authorities, before passing from the former's custody. It is shuddersome to think that such an order should be necessary, but that it is necessary no one at all conversant with the present disorder of things in many branches of the city government, can deny. The only possible thing to be said in mitigation of these horrors is that the bones and other tissues of the insane are often abnormally vulnerable, and therefore broken bones and extensive ecchymoses in these unfortunates are not evidence of such extreme degrees of violence as they would be in the mentally and physically sane.

News of the Week.

Pathological Society of Philadelphia.—At a stated meeting held June 27th, Drs. J. Chalmers DaCosta and R. C. Rosenberger reported "A Case of Trichinosis," and exhibited specimens from the gastrocnemius muscle. The patient was a young man, who had been apparently well until struck upon the calf of the leg by the pedal of a bicycle, following which the part was found to be enlarged and tender. Examination of a portion of excised muscle disclosed the presence of trichinæ. Eosinophilia was not marked, the number of eosinophile leucocytes in the blood at no examination exceeding four per cent. It was thought that the infection was an old one, which had been roused into activity by the traumatism. Dr. W. E. Robertson exhibited a specimen of "Polypoid and Ulcerative Colitis Due to Mercury." The patient had been an attendant upon a case of locomotor ataxia, and, it was believed, was intoxicated as a result of the absorption of mercurial ointment employed in administering inunctions. Dr. Robertson exhibited also "The Heart and Great Vessels from a so-called Blue Baby." The infant survived but two days, and upon postmortem examination the foramen ovale, as well as the ductus arteriosus, was found patulous. There was also a horseshoe kidney. Drs. H. D. Jump and J. D. Steele exhibited a specimen of "Polypoid Colitis with Adenoma of the Cæcum." The patient exhibited during life symptoms of the inflammation of the colon, with diarrhœa, the stools containing mucus and blood, but no tumor was palpable. Dr. W. W. Babcock exhibited a specimen of "Malignant Disease of the Adrenal Body with Secondary Invasion of the Kidney."

State Board of Medical Examiners of New Jersey.—At the annual meeting of the State Board of Medical Examiners, held at Newark, N. J., July 5, 1901, the following officers were elected: *President*, Dr. Charles A. Groves, East Orange; *Treasurer*, Dr. A. Uebelacker, Morristown; *Secretary*, Dr. E. L. B. Godfrey, Camden. Of the candidates examined, 20.4 per cent. were rejected.

Smallpox.—The records of the Board of Health show a slight decrease in the number of recognized cases of smallpox in the city during June, in which month there were 330 cases. In May there were 457, that being the largest number for any month this year. The total number of cases since the outbreak of the epidemic in November, 1900, is 1,521, and there have been 220 deaths from the disease in that period—a showing of which the New York City Health Commissioners can hardly be proud. During June one or more cases of the disease were reported from each of twenty-seven cities and towns in various parts of the State.

Investigating the Causes of Suicide in Chicago.—The number of suicides in Chicago has increased greatly during the past few years and the efficient Health Commissioner of that city has undertaken an investigation to determine the causes leading to this increase. He thinks that the mental depression so often accompanying and following an attack of influenza may be one of the factors present, and he has requested the Coroner to make special inquiry into the circumstances attending suicides, with reference to attacks of this disease.

Illegal Commitment of the Insane.—The daily press of Indianapolis has had much to say recently of an alleged "insanity trust," said to have been formed for the purpose of dividing the fees given for lunacy inquiries. Several young physicians are accused of having declared persons insane without any proper examination and even in the absence of the persons whose mental state was in question. A despatch from Indianapolis states that the County Medical Society recently held a largely attended special meeting at which resolutions were adopted censuring the physicians and others who have been identified with the alleged insanity trust, and calling upon the City Health Department to institute a rigid investigation of the charges of illegal commitments of the sane or insane.

Sanitary Matters under Civil Rule in the Philippines.—A despatch to *The Sun* from Manila announces that the Philippine Commission has passed bills establishing a Government biological and chemical laboratory there. Stations for the supply of vaccine virus will be established wherever necessary in the provinces. The laboratory and stations will be under a general superintendent

who will receive a salary of $4,000 a year. The commission has also established a Health Board, composed of a commissioner, at a salary of $6,000 a year, a sanitary engineer, a chief inspector, secretary, and laboratory superintendent. The chief army and navy surgeons and the dean of the Medical and Pharmaceutical Association are honorary members without the right of voting.

Gift of a Hospital Ship to the British Government.—The hospital ship *Maine* has been presented by her owner, Mr. Bernard M. Baker, of Baltimore, President of the Atlantic Transport Company, and by the committee of American women, who fitted her out for service in South Africa, to the British Government and formally accepted with thanks by the Admiralty. The vessel made two trips between Southampton and Cape Town and Durban, in charge of American surgeons and nurses, returning each time with several hundred wounded and invalided British soldiers. She was then sent to Taku to receive the sick and wounded of all the countries having troops in China. She returned to Southampton last January and has since been out commission.

The Deaths in New York State during May numbered 10,327, nearly 500 above the average for that month during the past five years.

Death of a Centenarian from the Heat.—Barney Martin, a park laborer in Brooklyn, who celebrated his 109th birthday on June 10th, succumbed to heat prostration during the hot wave last week. He was born in County Cavan, Ireland, and came to this country seventy-nine years ago. His occupation, until about ten years ago, was that of a cab driver. His claim to have lived in three centuries is said to have been authenticated.

St. John's Guild.—The two floating hospitals of this beneficent society began their daily trips to the Seaside Hospital on Staten Island on July 5th. Physicians and others may obtain tickets for free distribution to poor children at the offices of the Guild, 501 Fifth avenue. On account of the number of beds on the hospital boats being limited no well children over six years old can be received. All tickets must be signed by a physician.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy for the week ending July 6, 1901: June 29.—Surgeon T. A. Berryhill, detached from the Naval Laboratory, Brooklyn, N. Y., and granted sick leave for three months. July 3.—Asst. Surgeon J. H. Iden, detached from the Naval Hospital, Chelsea, Mass., and ordered to the Lancaster, July 8. Asst. Surgeon G. L. Angeny, detached from the Lancaster and ordered to the Naval Laboratory at Brooklyn, N. Y., July 8.

The Journal of Mental Pathology.—We have received the first number (June, 1901), of this journal, the aim of which is sufficiently expressed by the title. It is edited by Dr. Louise G. Robinovitch, and published by the State Publishing Company of New York. It will be published in ten parts, each year, appearing monthly except in August and September. The first number contains articles on "Psycho-motor Hallucinations in General Paralysis," by A. Marie; "Clinical Researches in Circular Insanity," by G. C. Ferrari; "Idiot and Imbecile Children," by Louise G. Robinovitch; "A Contribution to the Fissural Integrality of the Paroccipital; Observations upon One Hundred Brains," by E. A. Spitzka; "Suggestion during Natural Sleep," by P. Farez; "A Case of Verbal Blindness and Deafness and an Autopsy on the Body," by P. Serieux and F. Farnarier. There are also editorials, news notes, abstracts and reviews. The journal is neatly printed and shows signs of most careful editing.

Dr. S. Weir Mitchell was entertained on May 9 by the medical profession of Tokio and Yokohama, at a reception given in his honor at the Maple Club, Shiba Park. Addresses were made by Drs. S. Suzuki, M. Ogata, Kitasato, K. Miura, K. Takaki, and Stuart Eldridge, Baron Sanenshi, Surgeon-General of the Imperial Japanese Navy, proposed the toast in honor of Dr. and Mrs. Mitchell and Col. and Mrs. Schuyler, to which Dr. Mitchell responded.

The Plague shows no signs of diminishing in the several parts of the world where it has domiciled itself, but is rather increasing in many. The annual increase at Amoy and Hong Kong has appeared two weeks earlier than usual this year. It is impossible to collect satisfactory statistics of the disease, but U. S. Consul Johnson estimates that during the first half of May there were one hundred deaths a day in and around Amoy. At Marseilles a ship arrived on July 8 having had fifteen cases of plague among her crew of firemen. The passengers were removed from the ship, but will be quarantined in a house provided for the purpose by the Board of Health for ten days. The Bulgarian and Roumanian governments have established a quarantine of eleven days against pasengers from Constantinople, owing to the existence of the disease in that capital, and in consequence the Orient express service between that city and Western Europe has been abandoned.

The Army Medical Service at the Pan-American.—The United States Hospital Corps' camp, near the Government Building, is paved with broken stone, and is an exceedingly interesting exhibit. Dr. Edward L. Munson, captain and assistant surgeon U. S. Army, is in command, and there are 100 men under him. The camp consists of 22 tents. The hospital wards are composed of twelve "A" tents, set up in the form of a Geneva cross. There is a tropical ward, a winter ward, a summer ward. If the rest of the United States Army was represented in proportion to the hospital corps there would be over 5,000 United States troops on the grounds. The Hospital Corps and equipment station at the exposition are such as is usually assigned to an army brigade which contains 5,380 men.—*Buffalo Medical Journal.*

A New City Hospital.—Justice Truax of the Supreme Court has appointed commissioners of appraisal in the proceedings to be taken by the city to acquire land situated on Lenox Avenue, between One Hundred and Thirty-sixth and One Hundred and Thirty-seventh Streets, for the purpose of erecting the new Harlem Hospital. The value of the property to be acquired is in the neighborhood of $400,000.

The Heated Term.—One of the most severe and fatal "hot waves" of which there is any record in this part of the country occurred during the five days ending July 3. During that period the number of deaths from all causes in the city was 729, nearly 200 more than in the corresponding period in 1900. The number of deaths reported to the Health Department due primarily and solely to heat was 158, the greatest number in any one day being 61 on July 2. On that day there were 660 ambulance calls at nine hospitals, most of them for cases of heat-stroke, but the total number of prostrations was undoubtedly very much greater, for many were overcome in their own homes, and

others were taken away from where they fell in private conveyances. Horses suffered greatly, and the streets were literally encumbered with the bodies of the dead or prostrated brutes lying at intervals of two or three blocks. Many of the animals were already weak from the effects of the epizootic. In Philadelphia, for the week ending July 6, there were reported to the Bureau of Health, 857 deaths, 429 more than during the preceding week and 313 more than during the corresponding week of the previous year, and a larger number than has ever before been reported. Of this number 228 were of children below the age of 5 years, and 208 were attributed directly to sunstroke. The number of deaths in Baltimore for the week ending July 6 was 451, the highest number for a week of which the Health Department has any record. Of these deaths 236 were of children under five years of age. At least 50 per cent. of the mortality was said by the Health Department officials to be due, either directly or indirectly, to the intense heat.

Pink Eye in Newark.—A New York daily paper publishes a despatch from Newark, N. J., stating that the small boys who bathe in the more or less dirty waters of the river, canal, and bay, are suffering from sore eyes. The paper says that "physicians call the disease 'cayri neticite,' and they say it is caused by a germ in the water. It is contagious." The compositor must have had conjunctivitis himself who twisted the word into such awful shape.

An Epidemic of Anthrax Among Horses.—Planters in Bolivar and adjoining counties in Mississippi are alarmed by an epidemic of anthrax which is destroying their draught animals. The ravages of the disease are reported as being extraordinary, 90 per cent. of the work animals having perished in parts of the infected district. Numbers of planters have lost from 30 to 100 mules and horses and others have lost all they had. The disease has prevailed only a few weeks, and is rapidly spreading throughout the northern part of the State. The Pasteur serum is being extensively employed as a prophylactic in places threatened by the pest.

Alleged Discovery of the Bacillus of Syphilis.—In a paper by Drs. Louis Julien and Justin Delisle, read before the Paris Academy of Medicine on July 3, the writers claim that they have discovered the true bacillus of syphilis.

Infectious Diseases in Philadelphia.—During the two weeks ending July 6 there were reported to the Philadelphia Bureau of Health 225 cases of typhoid fever, 121 of scarlatina, and 98 of diphtheria.

Failure of the Skene Hospital Project in Brooklyn.—An order of the Supreme Court has been granted calling upon the creditors of the Skene Hospital for Self Supporting Women to show cause on October 9 why the corporation should not be dissolved. The corporation was organized on July 12, 1899, and the directors were Dr. A. J. C. Skene, John Claflin, Hugo Hirsh, Charles A. Moore, Alexander E. Orr, George F. Peabody, Royal F. Peabody, William H. Snyder and Spencer Trask. The object was to erect a hospital and dispensary for women, and was one in which Dr. Skene took a very special interest. Upon his death it was determined to establish the hospital as a memorial to him. It was estimated that the new building would cost about $300,000, but only $23,000 was subscribed, and of this amount only $3,261 was paid in.

Dr. Niels Finsen, of Copenhagen, the originator of the system of phototherapy which bears his name, is a young man of slender build, rather shy in his deportment, but full of enthusiasm and confident of the great value of his discovery. He believes that much more can be accomplished by his application of sunlight than by the x-rays in the treatment of lupus, ulcers, and many other affections.

Governor General Leonard Wood is suffering in Havana from an attack of typhoid fever. His illness was at first thought to be influenza, though some of the newspapers had it that the disease was yellow fever. It is gratifying to learn that the attack is mild, and that there is every reason to hope for a prompt and uncomplicated recovery.

The Pope Honors His Physicians.—A despatch from Rome states that Pope Leo XIII. entertained eight guests at luncheon in the Vatican on July 4th, in honor of his physicians, Drs. Lapponi and Nazzoni. Although the Pontiff has occupied the chair of St. Peter for twenty-three years, it is said that he had never before entertained any one at his table. In accordance with Vatican etiquette, the Pope's guests sat at a table in the center of the dining room, the Pope sitting alone at the table in an alcove window.

The Marion County (Ind.) Medical Society has received from Dr. J. Ewing Mears, of Philadelphia, some property in the city of Indianapolis on which to erect a building for a permanent home for the Society. The gift is intended as a memorial to Dr. Mear's father, who was one of the early physicians in that city.

The Cost of Patriotism.—The irrational method in which our national holiday is celebrated is shown by the great loss of life and property resulting from the recent observance of the Fourth of July. From such incomplete statistics as have been collected, it appears that nineteen persons were killed and 1,611 injured on that day by explosion of fireworks and the like. In addition, further deaths may be expected from tetanus. The loss of property by fire is estimated at about $60,000.

Obituary Notes.—Dr. HENRY C. WAGONER, county physician of Somerset County, N. J., died at his home in Somerville, from the effects of the heat, on July 1st. He was born seventy years ago and was graduated from the Medical Department of the University of Pennsylvania in 1853. He was one of the medical staff of the Somerset Hospital.

Dr. JAMES T. YOUNG, of Washington, D. C., died on July 3d. He had been ill about a year, having suffered an attack of apoplexy last summer. He was a graduate of the Bellevue Hospital Medical College in the class of 1864.

Dr. TABOR B. REYNOLDS died suddenly at Saratoga Springs, N. Y., on July 3d, at the age of eighty-one years. He was graduated in medicine from the Albany Medical College in 1842. He had been during his life more or less prominent in public affairs. He was an ex-member of the State Assembly, an ex-sheriff, and had filled other offices

Dr. AARON N. BRAMAN, of Rochester, N. Y., died on July 6th. He was a graduate of the Medical Department of the University of Buffalo in the class of 1851.

Dr. FRANK A. JELLECKER, of New York, died from heat prostration on July 3d. Dr. Jellecker was graduated from Bellevue Hospital Medical College

in 1892 and served as house surgeon to St. Mary's Hospital of Jersey City, and as district physician to Lying-in-Hospital of New York. He was an active and zealous practitioner, and leaves many warm friends in the profession in this city to mourn him.

Dr. HENRY C. C. MAISCH died at Philadelphia on July 1, at the age of thirty-eight years. He was a son of the late Prof. John M. Maisch, for many years a member of the Faculty of the Philadelphia College of Pharmacy, and one of the editors of the National Dispensatory. After graduation from the College of Pharmacy in 1885, Dr. Maisch continued his studies in the University of Goettingen, receiving the degree of Ph.D. in 1889. On returning to this country he became assistant professor at Clark University, Worcester, Mass., subsequently professor in the Illinois College of Pharmacy in Chicago, and later Professor of Materia Medica and Botany in the Medico-Chirurgical College of Philadelphia.

Dr. MARTIN H. WILLIAMS died at Philadelphia on June 30, at the age of thirty-nine years. He was graduated from Jefferson Medical College in 1887, and was subsequently connected in various capacities with the college and hospital. He was also consulting pathologist to the Philadelphia Lying-in Charity, physician to the Franklin Reformatory Home, and assistant physician to the Philadelphia Sanitarium. He was for two terms a member of the Board of Public Education.

Dr. JOHN K. CURWEN died at Harrisburg, Pa., on July 2, of heart-disease at the age of eighty years. He was one of the oldest graduates of Yale College (in the class of 1841) and of the medical department of the University of Pennsylvania (in the class of 1844). He was resident physician for seven years in the Pennsylvania Hospital. He was instrumental in building the State Hospital for the Insane at Harrisburg and was its first superintendent. Subsequently, in 1890, he became superintendent of the State Hospital for the Insane at Warren and continued in that institution until 1900.

Dr. MORRIS FUSSELL died at his home near Chester Springs, Pa., on June 29, at the age of seventy-five years. He was the oldest medical practitioner in Chester county, where he had been engaged in practice for more than half a century.

Obituary.

SAMUEL HAYNES, M.D.,

SARANAC, N. Y.

Dr Samuel Haynes died at his residence, Saranac, New York, June 26 aged seventy-three years and seven months. Dr. Haynes was graduated in 1852 from the Medical Department of the University of New York. He served as Acting Assistant Surgeon in the Carver and the Lincoln Hospitals, Washington, in 1864-65. Besides doing a general practice he made the affections of the eye, ear, nose, and throat a special study, and secured wide recognition for his skill in those lines.

He was a member of the Clinton County Medical Society, and belonged to the G. A. R. and the Masonic Order. He was always a hard student, and kept fully abreast of the times by reading numerous medical journals and by frequent visits to the hospitals of Philadelphia, New York, and Boston. His life and character need no eulogy other than the voluntary testimony of friends and neighbors of the towns in which he lived, and for over forty-five years practised his profession with the single purpose of faithfully discharging all the responsibilities of a large and varied country practice.

Progress of Medical Science.

Journal of the American Medical Association, June 29 and July 6, 1901.

The Relation of Nervous and Mental Diseases to General Medicine.—H. A. Tomlinson speaks of the mode of death in certain cases of chronic sickness. He notes that, no matter what the somatic disease, all the patients presented marked symptoms of uræmic poisoning, and the condition of the kidneys was confirmed by uranalysis. Death came in one of four ways: 1. suddenly, from apparent cerebral hæmorrhage; 2. in apparent collapse with syncope; 3. more slowly with dilatation of the right heart, pulmonary œdema, vasomotor paresis and asphyxia; 4. with apparent asthenic bulbar palsy, sometimes rapidly fatal, again accompanied by a mono- or diplegia, a hemi- or paraplegia, of varying degree of completeness, death resulting from progressive asthenia. Autopsy failed to reveal any evidence of gross lesion or degenerative change to account for the symptoms and conditions observed during life. This experience led to the systematic study of the urine in chronic cases, to determine if possible how far the nervous manifestations of uræmia might be anticipated. The author found that marked changes might be present in the structure of the kidney without the presence of albumin or casts, and in the absence of the ordinary clinical signs of nephritis. Also that in proportion, as the nervous symptoms of uræmia were present, were the ordinary somatic manifestations absent. Furthermore, he found that uræmic poisoning, fatal in result, might be present as the result of auto-intoxication from imperfect metabolism, acting through the vasomotor apparatus and bringing about the abeyance of the function of the kidney, as the result of vasomotor spasm producing ischæmia, and in the absence of any marked degenerative change in the kidney itself. That is, the function of the kidney as a filter was not interfered with, but the excretion of the solid constituents of the urine was diminished and the chlorides were often entirely absent, while, for obvious reasons, urea would not be diminished in amount. In cases of parenchymatous nephritis and of the diffuse form in which the medullary substance of the kidney was most involved, the diminution of the excretion of urea was the rule and albumin and casts were more common. This experience led him to study more carefully similar conditions among recent cases, and he found that practically all cases admitted to the hospital gave evidence of some degree of renal inadequacy. In the cases of so-called delirious mania and in delirium associated with other forms of insanity the evidence of imperfect elimination was marked; and furthermore success in relieving these conditions was always in proportion and in sequence to the re-establishment of the function of the kidneys. In those cases which proved fatal and had been accompanied by high temperature with vasomotor paresis before death, the change in the kidneys was found to be parenchymatous; while in those without elevation of temperature but exhibiting progressive asthenia the change in the kidney was interstitial. By following the same method in the study of the other vital functions, the intimate association between irritability, exacerbations of excitement, disturbance of the special senses, recrudescence of delusion, and impairment of digestion with constipation was determined.

Actinotherapy in Cutaneous Medicine; a Preliminary Communication. W. S. Gotthelf describes and figures an instrument called an actinolyte, which consists essentially of an arc light, with the necessary arrangements for automatic action, inclosed in an iron hood. In front of the arc is a double convex condenser, adjustable for focusing purposes by means of a rack and pinion. On rods that project in front from each side of the hood is a double convex focusing lens, also adjustable. By means of these rod-rests a circle of light of any size can be readily obtained; of course the smaller it is the more intense is the illumination. The hood is swung in such a way that it can be raised or lowered, and moved laterally and forward, thus making it possible to project the light-rays with accuracy on the area that is to be treated. On the front of the hood and between the hood and focusing lens is a cell for the purpose of containing the fluid to cut off the heat-rays. This cell is filled with distilled water, a special chemical, or alum solution, or it may be connected with the water-supply, for which arrangement is made, so that a continuous stream of heat-absorbing fluid may flow through the cell. The base of the instrument contains a switch-key with a selector on it. Either the continuous or alternating current may be employed. Several cases have been treated by Gotthelf, one of [illegible] results promise to be bril-

liant, and the other a case of tertiary ulceration of the leg. The advantages of this therapeutic method are: 1. It is eminently conservative. It causes no radiodermatitis, ulceration, or loss of hair, such as too often, though sometimes necessarily, occurs under the Roentgen treatment. 2. It is entirely painless. This is a great desideratum, more especially in dealing with women and children. 3. It is effective. New as the method is, there is already concurrent testimony from a sufficient number of competent observers to its utility.

Cæsarean Section Three Times in the Same Person in Six and One-half Years.—J. W. Coakley describes this unusual case, the nature of which is sufficiently indicated in the title. After each operation the patient made a good recovery.

New York Medical Journal, June 29 and July 6, 1901.

Notes on Ringworm.—A. Ravogli discusses first the nature of the malady and then passes to the important topic of treatment, saying that any substance capable of causing a shedding of the epidermis is efficient because the parasite goes off with the necrosed epidermic scales. Tincture of iodine, chrysarobin, resorcin, and pyrogallic acid are all commended, as is also mercuric chloride solution. When the disease has affected the hair and the hair follicles, the fungus becomes protected as it were, and here we must resort to epilation. The old Wilkinson ointment as modified by Hebra is recommended in these cases. Remedies producing pustulation of the scalp insure a thorough destruction of the parasite. Another plan commended is the application of the continuous current to the scalp, the positive sponge pole being impregnated with an antiseptic, such as a one per cent. solution of bichloride, and applied to the diseased patch, while the negative pole is applied at some distance. The current may be allowed to pass once daily for thirty minutes. Strong emphasis is laid on the contagiousness of the malady and thorough hygienic measures are advocated as the best means of prophylaxis.

The Mental Diseases of Childhood.—W. B. Noyes enumerates as genuine acute psychoses occurring at puberty the following: 1. Melancholia either simple, passive, or active, with excitement or stupor. 2. Mania, which may be simple, irritable, or of the nature of catatonia. 3. Mental confusion. 4. Hallucinatory madness, hallucinations being possible even in a young child, because sensory impressions become fixed early. The following progressive psychoses occur: 1. Dementia of puberty (dementia hebephrenica). 2. Simple precocious dementia. 3. Very rarely, general paresis. Of psychoses resulting from mental degeneration, there are: 1. Paranoia, which is very rare because delusions cannot appear in a child until systematized concepts or logical thought begins. 2. Periodic insanity, intermittent or circular, which is more common. 3. Phobias, obsessions, and *folie de doute*, which are not uncommon. 4. Kleptomania and dipsomania. 5. Sexual aberrations. 6. Impulsive insanity: imperative conceptions, suicidal or homicidal. 7. Moral insanity. There are also the following combined psychoses or neuropsychoses: 1. **Neur**asthenia, more especially cerebral neurasthenia. 2. **Hyp**ochondria, most commonly of a sexual nature. 3. **Hyst**erical insanity. 4. Choreiform insanity (the mental equivalent of chorea). 5. Epilepsy appearing as a chronic psychosis or a spasmodic dementia, or an acute psychosis as the psychical equivalent of epilepsy. Lastly, there may be psychoses by intoxication, of the nature of (1) auto-intoxication, (2) intoxication following infectious disease or (3) alcoholic intoxication.

Chronic Fluorine Poisoning.—F. Schwyzer reports the case of a journalist who was a large consumer of bottled beer, through the medium of which he contracted the poisoning took place. The general symptoms referable to chronic fluorine poisoning are thus grouped by the author: uninuclear leucocytosis, greatly increased excretion of lime in the fæces and great increase of its excretion in the urine, general pains in the bones (so-called osteomalakia and increased coagulability of the blood with a tendency to thrombosis. In addition fluorine can be detected in the urine by means of certain chemical manipulations described in the paper. Fluorine preparations have been regarded as non-poisonous and have been advocated for use in preserving foods and as therapeutic agents. The case of the author shows that the subject of this element should be used with caution.

Remarks on Appendicular Abscess.—R. Gunn states that one of the most important questions in the appendicular surgery of to-day is whether we should remove the appendix in abscess cases or not. It may be said definitely, he thinks, that in all large abscesses an effort should be made to remove it, but in the case of small recent abscesses, or multiple abscesses of short duration, it might be well to do so, provided the condition of the patient is good. In regard to counter openings he thinks that the smaller the incision and the fewer the number, the better. In almost every case one incision is enough. In some cases, however, when the abscess is under the cæcum or ascending colon, and we have to drain around a curve, a counter-incision in the loin may be of assistance. As the fascia is often deficient, a cross incision may be made in order to drain with ease. It can easily be seen how much more directly the drain can be inserted from below into the bottom of the abscess cavity, in the class of cases mentioned, than from above. When the abscess cavity has filled to the outer side of the gut it is no longer necessary to use double drainage, and we can drain from above or below, as we prefer.

An Improved Form of Ambulance would Increase the Value of the Treatment of Heat Prostrations.—F. Griffith advocates the use of a lining of asbestos or any of the various refrigerator materials on the side walls, ceiling, and floor of the ambulances. An electric fan might easily be attached and a supply of ice-bags could be carried for immediate use.

Philadelphia Medical Journal, June 29, 1901.

A Preliminary Report upon a Case of Uncinariosis (Ankylostomiasis).—Thomas A. Claytor declares that this disease has been diagnosed but rarely in the United States. The case reported was that of a boy of nineteen years whose development had been tardy both in mind and body. After examination of the blood there was strong inclination to the diagnosis of idiopathic pernicious anæmia. The red corpuscles numbered 1,577,000 (thirty-one per cent. of normal), the whites 4,400. The evacuations were then examined for the ova of the uncinaria duodenalis which were found. On this discovery thymol gr. xxx was administered, and repeated in two hours. Two hours after this castor oil was given, followed the next morning by magnesium sulphate. The patient began to improve at once after this treatment. There had been marked anæmia, swelling of the face, abdomen, and feet, great weakness, and dyspnœa on slight exertion. There seemed to be no gastro-intestinal disturbance. After the above treatment, the administration of iron and arsenic was at once begun with a full nourishing diet.

The Role of Infection and Intoxications in Diseases of the Spinal Cord.—Alfred Gordon believes that intoxications produce more deleterious effects on the spinal cord than on any other organ. An acute infectious intoxication of the spinal cord is characterized by a primitive alteration of the nervous tissue, consisting of congestion, but with a toxic vascular exudation, the contact with which is sufficient to produce foci of necrosis and hæmorrhages; sclerosis follows almost inevitably. The difference between a new and an old inflammation is that in the first case there is an immediate and rapid reaction, whereas in toxic lesions due to an old inflammation, we find no general reaction and less rapid involvement—but the result will always be the same. Various observations tend to prove that micro-organisms with their chemical products are apt to produce a disseminated sclerosis. Cases of multiple sclerosis have been reported as a result of intoxication with carbonic acid gas. Multiple sclerosis, with symptoms of progressive muscular atrophy, has followed influenza. In Landry's paralysis we always find a history of infection. The whole clinical picture of anterior poliomyelitis points to the presence of an infectious element. In muscular atrophies of spinal type, we often find a history of some acute infection or chronic intoxication. Cases of ataxia of spinal character have been reported after various infectious diseases. The infectious origin of myelitis seems to be an established fact. Transverse lesions of the spinal cord have been reported after infections. Amyotrophic lateral sclerosis due to lead intoxication has been reported. The nervous system in general and the spinal cord in particular can be attacked by infectious, secondarily and primarily. The writer believes that infections and intoxications of various character constitute the most frequent and the most active causative element in diseases of the cord. The day is not far distant when orthotherapy will be used extensively in diseases of the nervous system.

American Medicine, July 6, 1901.

Experimental Yellow Fever.—Walter Reed, James Carroll, and A. Agramonte all report two important experiments in connection with the possible importation and propagation of yellow fever. They believe that the results of their experiments indicate that the period of incubation in yellow fever is usually exceeds the seven days now generally accepted, although exceptional

this must not be left [illegible] to isolation. They also believe that their views serve to emphasize anew the importance of the recognition by the profession of mild and very mild cases of yellow fever. Guiteras says: "I cannot insist too much upon the importance of the diagnosis of the first case of yellow fever in a locality. Undoubtedly the cause of the epidemic of yellow fever is to be found in the introduction into a community of cases that are not suspected to be yellow fever." In the light of their investigations, the writers believe that the failure to detect cases of mild yellow fever has been the most important factor in the development of the theory of the propagation of this disease by fomites.

Medical News, July 6, 1901.

Practical Notes Relative to Rabies.—N. G. Keirle declares that if there is a suspicion of rabies, the patient should be treated without delay. Delay is not only dangerous, but may be deadly. The length of time of treatment should not be less than 23 days. If the bite was severe, and there is persistent induration about the wounds, it is advisable to continue treatment off and on until the induration subsides. Unless it is certain that rabies is absent, those exposed should not be held pending investigation. If the animal can be securely kept, it is a mistake to kill it. Treat the patient and observe the animal. If after a few days the latter is evidently in sound health, the treatment may be stopped. There is no serum antitoxine analogous to that of diphtheria. The material used is a part of the spinal cord of a rabbit that has died of rabies. This is rubbed up in sterile cool water. The method of treatment is by means of hypodermic injections, generally in the abdominal region.

The Boston Medical and Surgical Journal, July 4, 1901.

Report of a Case of Porro-Cæsarian Section for Placenta Prævia Centralis.—N. J. Gillette reports a case in which none of the old methods could be used with success, as the os was dilated but little larger than a ten-cent piece and every attempt at forcible dilation was accompanied by hemorrhage, and tampons could not be packed tightly enough to prevent blood escaping. The patient's condition was such that another hemorrhage would be likely to prove fatal. Cæsarian section was performed and a child delivered and resuscitated. The placenta was removed, but the uterus would not contract, and hemorrhage was again threatened; consequently the uterus was amputated. The patient made a good recovery and returned home at the end of four weeks, well except for pallor and anæmic headaches. The child is now, at four months, a big, healthy baby.

The American Journal of the Medical Sciences, July, 1901.

Primary Tuberculosis of the Pericardium.—David Reisman concludes that tuberculosis of the pericardium is comparatively common. It may be primary in the clinical, rarely in the pathological sense, or it may be secondary. The primary form is either a hæmatogenous infection or is the result of extension by contiguity from some trivial focus. The most frequent source of infection is a tuberculous mediastinal or bronchial lymph gland. The primary form is usually chronic, and appears as an obliterative pericarditis. In a large number of cases there is an associated mediastinitis, with adhesions to the pleura, sternum, and ribs. The symptoms are those of adherent pericarditis or mediastino-pericarditis. In every case of obliterative pericarditis of obscure etiology, tuberculosis should be suspected, particularly if there are no endocardial murmurs. The diagnosis of this affection can usually be made only by excluding other causes, except in rare instances of successful animal inoculation with fluid obtained by tapping a pleural cavity. There may be no characteristic features at the autopsy, so microscopical examinations should be made in every case of adherent pericardium before tuberculosis is excluded. In rare cases a clinically primary case is acute, the exudate being serofibrous, hemorrhagic, or purulent.

Gonorrhœal Myositis.—Martin W. Ware reports the case of a man thirty-five years old who in the fourth week of an attack of gonorrhœa had a chill and fever, with pain in the left knee-joint. There was no evidence of joint trouble. Later there developed severe pain about the shoulder joint, and a mass the size of a walnut was felt in the muscles. The overlying skin was movable. The daily elevation of temperature was to about 102° F. In a few days, although iodine was applied locally, the mass grew, and the pain became so severe that incision was resorted to in the expectation of giving an opening to pus under tension. The muscles were sodden, of a grayish color, and further in depth very friable. Although no pus appeared, there was a free oozing of turbid serum. Relief from pain followed, but the induration extended. The cover-glass smears showed diplococci, but not other micro-organisms. The section of the muscle showed interstitial inflammation. There was cloudy swelling. There was some shrinkage from the perimysium, and the nuclei in places showed a tendency to multiply which may be a sign of regeneration. The connective tissue proliferation largely increased the interval between the individual muscle fibres and also compressed them. Sections stained for gonococci showed nothing of the muscle structure, but a liberal scattering of diplococci grouped about the nuclei and in the interstices of the muscle fibres. This location of the gonococcus is explained either as a metastasis in the muscle or as an extension of inflammation from neighbouring joints or bones.

The Lancet, June 22 and 29, 1901.

Sugar-Free Milk as a Food for Diabetics.—R. Hutchison has devised a milk preparation which contains all the original casein and salts along with a certain additional proportion of fats. It is practically sugar-free, and appears like an unusually rich ordinary milk. The following diet-schedule is suggested:

BREAKFAST.—Bacon; eggs scrambled with butter; fish with butter sauce, or some form of cold meat; toasted protene bread with plenty of butter; and café-au-lait made with sugar-free milk and sweetened with saccharin if desired.

DINNER.—Soup (without vegetables or other carbohydrate-containing matter); fish (preferably one of the fatter sorts); meat with green vegetables and melted butter; custard of eggs and sugar-free milk; and cheese with protene bread and watercress. Beverage: whiskey and water or any dry natural wine.

SUPPER.—A cup of well-made beef-tea; eggs in some form—e.g., as an omelette with as much butter as possible; fish or cold meat; and cheese with protene bread and butter and a salad with plenty of salad oil. Beverage: a glass of sugar-free milk.

The rest of the milk, sufficient to make the total daily allowance up to three pints, should be taken as a beverage between the chief meals.

Meat Preparations; the Possibility of Myosin Albumin.—F. W. Forbes Ross says that many of the meat preparations now on the market are faulty, from a physiological point of view, because they contain one solitary constituent property from meat and in some cases from blood, and often this particular constituent is by no means the most nourishing. The nutritive, formative, and reparative principles are discarded for those which are at the best merely stimulating. He advises the use of mixed albumins from meat, using to designate the compound the comprehensive term "myosin-albumin." This is especially serviceable, not only by reason of its own inherent nutritive values, but also because it can be prepared in so many different ways. It forms the ideal ration for the soldier and is also useful in disease.

Acute Cardiac Failure.—Richard Douglas Powell, in the Cavendish Lecture, mentions among the causes of this accident direct injury, as when a healthy man ruptures, during a violent exertion, one of his aortic cusps, the displacement of a clot from a systemic vein, and cardiac failure from over-taxation. There are always two factors at work, direct fatigue of the nervo-muscular tissue and a poisoning of the blood from an auto-metabolic source. Among the concomitants of heart distress or failure during violent exercise, as running, vomiting is one of the most common. One of the most constant after effects is anæmia. Gastro-intestinal attacks, vomiting, and diarrhœa are not uncommon occurrences in those who, habitually leading a sedentary life, suddenly take to exhausting exercise. The heart of a child between six and twelve is, according to the author, relatively hypertrophied, which is to be ascribed to the ceaseless activity at this age. A point often forgotten in the case of young children is their special aptitude for short spells of active exercise, but their complete unfitness for prolonged monotonous exertion. The treatment of acute cardiac failure from overstrain involves a few weeks of rest and many months of careful supervision. In many there is a feeble lung capacity, and for such cases well-ordered respiratory exercises are of great utility.

The following are the special factors in acute cardiac impairment in acute disease: (1) maloxygenated and otherwise contaminated blood-supply to heart muscle and nerve, (2) excessive weight of blood burdening the heart; (3) exhausted innervation from sleeplessness and physical cardiac fatigue, (4) positive obstruction to the flow of blood through the lungs; and (5) changes in the texture of the heart muscle incidental to the disease and especially to the pyrexia. Now the first two indications are undoubtedly met by depleting the blood volume from the venous side by attention to secretions, the occasional

use of mercurials, careful limitation of the food taken in place of the over-feeding often to be observed, and in some cases a small blood-letting.

Oxygen inhalations are also of service. For the third and fourth indications in the foregoing list we possess no better remedy than strychnine, which is best given by syringe in case there is much abdominal distention. The fever should be kept within bounds by any well-approved method.

Practical Points in the Treatment of Threatened Asphyxia.—For the purpose of restoring respiration R. L. Bowles believes that the best method is that of Marshall Hall, modified to embrace the corrections of experience. (1) It is truly a very "ready method" and requires no apparatus; (2) the instructions are easy to be understood by ordinary unprofessional people; (3) on account of the immediate adoption and continued use of the prono-lateral positions this method is more to be trusted than any other for keeping the pharynx clear of obstruction; (4) it empties the stomach and gradually clears the lungs of the watery and frothy fluids, and it will surely and gently introduce sufficient air at each inspiration to take the place of the fluid which has been expressed; (5) the pressure applied to the back when the patient is prone exerts an influence on the heart, the blood is moved onwards towards the lungs which are, by the next movement, opened up to receive it, and thus the right side of the heart and the cerebral vessels are relieved of the engorgement which we know to exist; (6) the safety of the patient is more perfectly secured by keeping him on one side during the whole treatment, one lung being thus kept quite free; and (7) in apnœa, or, after a time, in drowning, when the upper lung is believed to be freed from water and frothy mucus, if more air is required, it can be introduced by elevating the upper arm above the head each time the patient is turned on his side, an addition, in part, of the Silvester to the Marshall Hall treatment.

Asparagus and Hæmaturia.—By J. S. Mackintosh. The patient, a man of 73, passed considerable blood in the urine and the kidney was detected as its source. The only cause that could be assigned for the occurrence was the fact that the patient had eaten heartily of asparagus. This vegetable, says the author, is a stimulant diuretic causing dilatation of the afferent and contraction of the efferent blood-vessels of the kidney. The patient, then, with the kidneys engorged with blood exposed himself to a thorough cooling of the surface of the body. The mode of production of the hæmaturia seems plain enough. What is not so clear was its transient character. Apparently, a train had been well laid to lead to an explosion of an acute nephritis, but ended, happily, in a mere fizzle. The patient himself was, for his years, remarkably active, both in mind and body. Of spare habit and small stature, he enjoyed, as a rule, excellent health, beyond occasional slight "uricacidity" manifestations. He exhibited a degree of arterio-sclerosis not uncommon at his age, but of chronic interstitial nephritis no symptoms at all.

The Early Operative Treatment of Acute Mastoid Inflammation.—Edward B. Dench, describing the symptoms of mastoid involvement, says that the pain is apt to be severe; there are headache and sleeplessness and in children a considerable rise in temperature. Temperature is of but little value in determining the presence or absence of any inflammatory process within the mastoid. Remembering the possible fatal issue, it seems advisable to urge early operative interference in all cases of acute middle-ear inflammation, and especially in cases following influenza or, in fact, any acute infectious disease. The writer states that attempts to abort inflammation of the mastoid have proven most unsatisfactory in his hands. The first step in the relief of acute middle-ear inflammation is the early and free incision of the membrana tympani, the incision being extended well out and upon the upper and posterior wall of the canal, so as to relieve any tension in the mastoid process. If after this all tenderness does not subside within a few days, he is in favor of opening the mastoid process. In no instance has he ever opened the mastoid process without finding considerable destruction of osseous tissue. He has never found the mastoid in such a condition that he would have been warranted in delaying the operation. As to the symptoms which warrant operative interference upon the mastoid, local tenderness is the most constant and the one most to be depended upon. It is usually found over the region of the antrum. The dangers of operative interference under proper antiseptic precautions are practically *nil*.

A Case of Lobar Pneumonia with Hyperpyrexia; Recovery.—Wm. R. Williams reports this case. The patient was a man 25 years old. There was severe pain in the left chest upon [illegible] rusty and very [illegible]. The heart action accelerated. Delirium [illegible] present to a [illegible] during the day [illegible] perature was highest on the second day, what 107.4° F. The urine [illegible] contained 25 per cent. by volume of albumin. Many casts were found for some weeks. On the [illegible] day the urine was normal and remained so. The physical signs were the typical signs of [illegible] pneumonia with serious pleurisy over the [illegible] left lung. The treatment consisted in the administration of whiskey and strychnine, nervous sedatives, and [illegible]. The temperature fell on the ninth day and the delirium ceased.

Forced Flexion and Adduction in Cases of Extreme Sensitiveness of the Hip-Joint.—E. H. Bradford relates a case in which all methods of treatment failed to relax the hip-joint at will, and to counteract the resulting spasm of the muscles about it. Under ether a plaster-of-Paris bandage was applied to the limb, which was flexed and slightly adducted. The result was a complete cessation of night cries. A month later the limb was again fixed in a straight splint with traction, and a recurrence of the night cries took place. These were again checked by fixation in a position of forced flexion and adduction without traction. The procedure seems applicable to such cases of an extreme type when other measures have failed. It is, of course, a temporary measure, and is successful only when applied with care. The child is secured upon a bed-frame lying on the back, to prevent rolling, and the flexed and adducted thigh, secured in a plaster splint, is slung so that the weight may not be an inconvenience.

Double Ureter of the Right Kidney.—Charles L. Scudder reports this case occurring in a child twenty months old. Without previous warning, the child became ill. She first was restless and vomited, later complaining of stomach-ache. She appeared dull and feverish. The bowels moved naturally after a dose of castor oil. The next day the child was very ill and looked pinched and distressed. The pulse and respiration were both accelerated and the temperature was 102° F. A soft, elastic, movable, slightly tender, sausage-shaped tumor was palpable in the right side of the abdomen. On the third day an enema caused a normal fecal dejection. The child was restless and crying out as if in pain. She appeared septic. There was an indefinite soft and elastic mass extending from the middle of the iliac crest nearly to the symphysis pubis. The temperature was fairly constant at 103° F. The pulse was about 140. Laparotomy was performed and the tumor was found to be retroperitoneal. The child's condition precluded further operation. She recovered from the anæsthetic and died the next morning. The anatomical diagnosis made at the autopsy was as follows: Duplication of the right ureter and renal pelvis. Agenesis of the orifice of one ureter and extensive dilatation, elongation, and tortuosity of the same with a hydronephrosis and pyelonephritis of the corresponding portion of the kidney. Slight hydronephrosis and dilatation of the ureter of the remaining portion of this same kidney.

Bronchial Concretions.—L. W. Arlee presents an interesting account of a man aged twenty-nine years who was admitted to the hospital with the diagnosis of bronchitis. Physical examination of the thorax [illegible] revealed some dry, hard, small, harsh rales in the anterior part of the left chest at the second interspace in the parasternal line. The temperature was 101°; pulse, 94; respirations, 24. There was sharp pain increased by cough, referred to this spot, and also to the right during cough. The sputum became slightly purulent. By the twelfth day the temperature began to show a septic character, and the sputum was very profuse and intensely fetid. On the fourteenth day, during a paroxysm of coughing, the patient expectorated a mass of about ½ of an inch long, conical in shape, the largest diameter being about ¼ of an inch. It gave off concretions for lime and phosphates. It is supposed that this concretion had been latent in the bronchus for a long time, and that in some way it was dislodged, and began to act as an irritant. This led to inflammation, and hence the bronchitis, the pneumonia, the pleurisy, and the feeding and expelling of the bolus.

The Malaria of the Tropics.—Bartle Leo Wright states that the predisposing causes of malaria are, in hot climates, summer seasons, low marsh lands, [illegible] decaying vegetable matter, and the presence of certain species of mosquito, the Anopheles being the only exciting cause is the plasmodium. Laveran [illegible] admission into the blood of the [illegible]. The tendency in all malarial [illegible] is for the [illegible]

Berliner Klinische Wochenschrift, June 17, 1901.

The Enterogenous Nature of Severe Anæmias.—E. Grawitz says that every case of severe pernicious anæmia is to be regarded as secondary either to known diseases like cancer or malaria, or to the presence of known or unknown poisons such as carbonic oxide, possibly lead, the poisons of intestinal parasites and of albuminous decomposition, to chronic minute hemorrhages or to change in the bone marrow, and that in almost every instance it is now possible by careful and patient investigation to find the cause of the blood changes. Keeping this in mind it is evident that the proper way to look at such diseases is to consider the blood lesion simply as a very prominent symptom and to group the cases according to the underlying causative factor. Hunter's theory of absorption of the products of oral sepsis does not cover the whole field while the importance that has been ascribed to atrophy of the gastric tubules, the disturbances of nitrogen metabolism, the presence of intestinal parasites, etc., is exaggerated, for all of these conditions may and do exist without the production of serious blood changes. The conclusion is that something more, probably an individual predisposition is required. The results obtained in treating the disease may sometimes prove valuable in deciding the etiology, for example, the author has permanently cured a number of cases by intestinal antisepsis and the use of a very carefully selected easily digestible diet, proving the enterogenous nature of these cases.

A Case of Pulsation of a Cicatrix of the Tympanic Membrane.—F. Grossman describes a case which is interesting because the detection of an anomaly in the ear gave a clue which resulted in the discovery of serious systemic disease. The drum membrane of a middle-aged woman who was troubled with tinnitus and deafness showed, in addition to the normal cone of light, a second bright streak which pulsated synchronously with the radial artery. As the pulsation was not rythmical a cardiac lesion was suspected, and a thorough physical examination showed the presence of a parenchymatous goitre, the size of a hen's egg compressing the right carotid, with secondary dilation and hypertrophy of the left ventricle and relative mitral incompetence.

Muenchener Medicinische Wochenschrift, June 18, 1901.

Pathological Alterations in the Bile.—L. Brauer publishes a number of experiments on artificially produced changes in the bile, and among the more important results noted is the fact that certain poisons, notably ethyl and methyl alcohol, appear in this secretion soon after their administration. A further significant observation is that these same agents are capable of producing an easily recognizable albuminocholia which persists up to the third day and that amyl alcohol seems to be more intense in its action than ethyl alcohol. Microscopical examination of the bile sediment also revealed the presence of distinct cylindrical epithelial casts which were sometimes branched, and after the addition of potassium iodide fine, frequently spiral cylindroids were found. In addition some large polygonal cells, with large central nucleus and granular protoplasm, resembling liver cells were seen. Since the liver is the first organ to receive the blood from the portal circulation, which is charged with the products obtained from the intestine, it is especially susceptible to pathological alterations as the result of intoxications, and the demonstration of the presence of appreciable amounts of alcohol in the bile throws an added light on the theory of the causation of the alcoholic cirrhoses.

Gonorrhœal Exanthemata in Infants.—J. Paulsen reports a number of cases which lead him to conclude that skin lesions in infected infants are much commoner than in adults suffering from gonorrhœa. The eruption consists of vesicles containing pus which on microscopical examination is found to contain the gonococcus in abundance, and this is the only way in which the diagnosis from other innocent eruptions can with certainty be made. Either an ophthalmia or primary infection through the skin may give rise to this cutaneous metastasis which in severe cases may go on to the development of furunculosis and glandular suppuration. The treatment consists in cleanliness and in opening the larger vesicles, after which the gonococci rapidly disappear and are replaced by other micro-organisms, and then recovery promptly follows.

Typhoid Infection from the Cadaver.—W. F. [illegible] that [illegible] cases of typhoid fever contracted [illegible] performance of post-mortem examinations [illegible] been reported, and adds a third in which he [illegible] the victim. There is no doubt that his sickness [illegible] typhoid, and all possibilities of the usual [illegible] fection could be excluded, since the locality at [illegible] was entirely free from endemic disease and [illegible] source possible lay in the body of a typhoid [illegible] autopsied three weeks before the first symptoms appeared.

Deutsch. Medicinische Wochenschrift, June 20, 1901.

The Tuberculin Treatment of Pulmonary Tuberculosis.—Goetsch ascribes the failures of the tuberculin treatment and the consequent discredit into which it has fallen to the fact that when the substance was first introduced it was recklessly used in too large doses and in wholly unsuitable cases. He himself has certainly its use for ten years and has obtained gratifying results by giving it in very small doses till tolerance was established and by adhering strictly to certain precautions. Out of 175 patients treated in this way 125 are to be regarded as cured, the average length of treatment being 198 days. The first principle consists in never injecting tuberculin into a febrile patient. The temperature must always first be reduced by rest in bed and packs, and the general condition must be sufficiently good not to preclude all hope of success. The injections are made twice a week starting with a dose of 0.00001 g. of the old tuberculin. If this is followed by too strong a reaction the dose must be diminished to 0.000001 g. and in some cases it may be necessary to have recourse to the new preparation Tuberculin R., which is weaker before tolerance can be established. By gradual increase it is possible to raise the dose to 1.0 g. of old tuberculin, the precaution being taken never to increase the amount until the preceding injection has failed to cause any reaction and also to keep the patient in bed on the day of and the day after the injection. Carried out in this way the treatment is safe and cures, as manifested by the recession of physical signs and disappearance of tubercle bacilli, are regularly observed.

The Treatment of Laryngeal Tuberculosis.—G. Pesdu is an advocate of active local treatment which may advantageously be carried out by the use of lactic acid, the curette, and the galvano-cautery. As an astringent lactic acid does good service in a strength of twenty to thirty per cent. but as a disinfectant fifty to sixty per cent. should be used, and for cauterization seventy-five per cent. or even the concentrated acid is required. In solution of medium strength it acts well in producing a covering for fresh wounds, but it should always be carefully localized in its application and not be blindly painted on. Curettage should always be vigorous and if possible the whole thickness of the mucous membrane should be removed, leaving the submucosa exposed. Small lesions are often best treated by touching with the galvano-cautery, which should be kept at a white heat and not allowed to scorch the adjoining areas, which is the result of using too low temperature and causes disagreeable secondary inflammations. In severe cases heroic surgical treatment offers the only chance, even the entire epiglottis may be removed without impairing the power of deglutition.

French Journals.

Is Leprosy Contagious?—Dom Santon states that the careful and impartial study of this subject shows that leprosy is contagious, this power of contagion is not often exercised, hygiene and cleanliness render it almost *nil*; occlusive dressings, asepsis, antisepsis, and disinfection are sure means of protection. The question of danger of contagion is much more simple than one would think. According to Hansen, "in order that leprosy be communicated, there must without doubt be much uncleanliness." However, the observance of the conditions mentioned above will effectively prevent the contagion.—*La Presse Médicale*, June 15, 1901.

Umbilical Hernia Containing all the Abdominal Organs.—Alain reports the case of a woman of twenty-six years who menstruated at fifteen years, and had suffered from gonorrhœa, but not from syphilis. She was pregnant for the ninth month when she entered the hospital. The fœtus remained immovable and had to be delivered by forceps. All of the abdominal organs were imprisoned in an enormous umbilical hernia. The child had only one eye, and lived a quarter of an hour. The cord was voluminous and the three vessels were separate.—*Journal de Médecine de Bordeaux*, June 16, 1901.

Therapeutic Weekly, June, 1901.

Principles of Cardiac Therapeutics in Recent Valvular Disease.—Eli H. Long divides the cases of actual cardiac disability into (1) valvular, (2) myocardial, and (3) nervous. From the first indication of endocarditis the important element in treatment is absolute rest—rest in the recumbent posture, mental rest, and the avoidance of any strain upon the heart. This should continue beyond the acute stage until the heart is fully able to do its work while the body is at rest, and the return to activity must be so graduated, that the compensatory process will keep pace with the demands upon the heart up to the full requirement. Before the patient is allowed to get out of bed, he should have a series of exercises which will very gradually increase the work of the heart. They should first be passive. The pulse should be carefully watched. Anæmia and other general conditions must be appropriately treated and elimination be constantly attended to. Frequent sponge baths are valuable. Capillary exercise, such as daily cold bathing, frictions, and gymnastics are most advantageous after the stage of recumbency. Cardiac stimulants, as a rule, are not necessary. The use of strychnine, without greatly stimulating the heart, will maintain a proper nervous tone of the whole circulatory apparatus. Digitalis would be indicated as an emergency drug. When the point of perfect compensation is reached, the patient is dismissed with directions as to the future manner of life.

The Use of the Aqueous Extract of the Suprarenal Capsule in Disease of the Ear.—W. H. Bates concludes that the aqueous extract of the suprarenal capsule improves the hearing of otitis media temporarily. Permanent benefit follows after the use of other treatment according to the indications. The extract is, he says, the most valuable known remedy for deafness.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL SUNDAY—A MEDICAL BILL—WAR DEPARTMENT—NATIONAL HOSPITAL—ANTI-MALARIAL EXPEDITION—CROONIAN LECTURES—ROYAL MEDICO-CHIRURGICAL SOCIETY—ALCOHOLIC ASCITES—CRAMMING IN PHTHISIS.

LONDON, June 21, 1901.

LAST Sunday was Hospital Sunday, and there was the usual collection at the various places of worship. Many donations were sent in advance to the Lord Mayor, some of them very munificent. Mr. George Herring sent his cheque for £10,000, with a sympathetic letter. This is his third donation of that sum. Sir Fred. Cook, Bart., sent £4,000. St. Michael's, Chester Square, again heads the church collections. Altogether, up to yesterday, the Lord Mayor had to acknowledge £25,000, which is about £1,000 more than at the same period last year; so we may expect the total to equal and perhaps exceed that of 1900.

A Medical Acts Amendment Bill was introduced to the House of Commons on Monday by Sir R. Jebb, Member for the University of Cambridge. It is to enable the Medical Council to suspend, for limited periods, practitioners guilty of certain offenses, also to enable the corporations to forfeit the diplomas of persons struck off the register, and to make penalties under the medical acts payable to the Council. The bill is well backed, but the session is rapidly passing, and many measures will be sacrificed.

The Minister for War is exciting much discontent by his treatment of the medical service. I told you the Director General had retired, but his successor has not been notified, though it is believed he has been virtually appointed. The same thing is said about the committee of experts. We are going to give Surgeon General Jameson (retiring Director General) a complimentary dinner. All the most eminent men are expected to be present, and it is to be hoped that some straight truths will be spoken for the Minister's warning.

The report of the Committee on the National Hospital for Paralysis and Epilepsy is a strong condemnation of the board of management and a complete vindication of the staff.

The fifth expedition to West Africa, organized by the Liverpool Tropical School, is now on the water, having set sail on Saturday. Major Ronald Ross and his colleagues were entertained at a dinner by a most distinguished company, including the Bishop, the Lord Mayor, the Principal of University College, and the Director General, I. M. S. Major Ross, who has been elected F. R. S., and has retired from the Indian Service, spoke in enthusiastic terms. They were not going to prove the mosquito theory, he said, as that had been conclusively proved three years ago; it was a matter of absolute certainty, only doubted by some amateur pathologists who were ready to deny confidently what is now accepted by every scientific man in Europe. They were going to prove the applicability of the theory to the prevention of malaria. They might not be able to exterminate the mosquito, but he was satisfied they could reduce its numbers to one-tenth or even to one-twentieth. They would begin with Freetown, and try to clear it of mosquitos.

I am reminded by this remark about reducing the numbers, that even in England we can scarcely say that mosquitos are exterminated. Indeed, in some districts they have in recent summers proved rather troublesome. The varieties have not been determined as a rule. But during the last year competent authorities have shown that some specimens of anopheles hibernate in this country.

At the meeting of the Royal Medical and Chirurgical Society, on the 11th inst., a letter was read signifying that the King accorded his patronage to the Society, and the President (Dr. Pavy) reported that His Majesty had since signed the roll, which had previously been signed by Queen Victoria and by William IV. The President also reported the reception by the King of the deputation for presenting an address of condolence on the death of the late Queen.

Dr. Campbell Thomson then read a paper on the prognosis and treatment of ascites in the course of alcoholic cirrhosis of the liver, in which he referred specially to the treatment by laparotomy, which has recently been advocated. From a consideration of published cases, he did not think there was sufficient evidence that this was superior to the simpler plan of tapping. Patients with ascites due to some associated condition might survive repeated tappings and even apparently recover; but when ascites was directly due to the cirrhosis, they rarely lived long after the first tapping. Cirrhosis might, in fact, go on for years, and even without definite symptoms, but all the while ascites was liable to occur from complications, the most common being peritonitis and perihepatitis. This ascites was often relieved and occasionally disappeared, the former state of latent cirrhosis remaining. Later, this cirrhosis might itself bring on ascites. Then tapping was of no avail.

Dr. P. Weber and Dr. H. White agreed with Dr. Thomson. The first mentioned that the specific gravity of the fluid drawn off should always be taken; if high, say 1,020, or nearly so, inflammation was present. Dr. White had found but about half the cases of cirrhosis met with in the post-mortem room had presented no symptoms of it during life, and the same was the case with granular kidney.

The attention of the Society was next occupied with an elaborate research into the metabolism in phthisis, carried out in Prof. Vaughan Harley's laboratory by Drs. Goodbody, Bardswell, and J. E. Chapman, in respect to cases selected by Dr. Fowler at the Brompton Consumption Hospital. Experiments were made first of all to determine the normal metabolism of some healthy persons. Then these persons were placed on excessive diets, which were always badly supported. In tuberculous patients over-feeding was much better tolerated, but even in these excessive cramming brought on anorexia, dyspepsia, and intestinal putrefaction. Moderately large diets gave the best results, and could probably be continued indefinitely. These moderately large diets were best borne by patients who had lost much weight. Those whose weight was normal, or nearly so, gave much less favorable results, as also did those whose disease was arrested. On the whole, absorption of nitrogen was good, even in pyrexia; of fats, still better, even when large quantities were taken.

The best results were obtained when the least discomfort was produced and dyspeptic symptoms were a sure indication of deterioration. When cases are becoming quiescent, or the patient is approaching his normal weight, the food must be diminished, but should still be more substantial than in health.

It seems that over-feeding has a rational basis, and, combined with open air, as in a sanatorium, may be of great value. On the other hand, this research appears to show that "cramming" may easily be pushed too far. Moderation gives the best results. Dr. Bardswell thought the diet should be fixed according to the loss of weight and degree of pyrexia in each case, and if a patient put on an increase of a pound per week, his lungs would do better than with more rapid increase. Dr. H. White had come to a similar conclusion from observations of cases under the Weir-Mitchell treatment. The fat was nearly all absorbed. He had never obtained nitrogenous equilibrium, and suggested that the deficit of nitrogen might

possibly be stored up in the tissues in some other form of proteid.

Dr. Goodbody said they had attained nitrogenous equilibrium in three instances during four weeks observations on six patients, giving twenty-two different periods for investigation. But there was no easy way of obtaining exact information. The best plan was to estimate the total nitrogen in the urine and fæces.

The nervous system has again been selected as the subject of the Croonian lectures. Professor Halliburton is this year's lecturer, and he devoted his discourses to the chemical side of the system which has been perhaps more neglected than the anatomical or clinical. He remarked at the outset that the scalpel and microscope have not been successful in discovering the mind, and no one would expect to find it in the test tubes of the chemist. Nevertheless, he said there are a large number of interesting chemical facts in connection with the nervous system which are not devoid of pathological importance which he proposed to lay before the college. He would dwell especially on the researches made by himself and workers in his laboratory, that being in accordance with the Croonian trust, and not because the work of other laboratories was less important. Much of what he said he considered would supplement Dr. Mott's course last year, and to him and Dr. Brodie he expressed special thanks.

The Medical Council was not able to be as expeditious as was hoped, and so had to sit on Tuesday. If the members could but realize the absurdity of debating the method of procedure on every occasion, there would be more rapid progress. It is strange that gentlemen in their position are not more anxious to get away to their pressing occupations. The abbreviation of speeches has often been urged upon them, but of equal importance is a less frequent return to futile discussions on indifferent matters. This has an important bearing on the finances, which are in a parlous condition. The accountant called in to advise on them furnished his report, showing a deficit on the year's working of more than £1,000. He suggests that the fees for attendance be reduced, that those for traveling days be abolished and payment of actual expenses substituted, and that steps be taken to shorten the sessions. He would thus effect a saving estimated at £1,400. I suppose no one would consider the fees for attendance excessive for any individual. But the Council is too numerous, and its discussions are too often tedious and prosy. It is obvious that some drastic change is imperative to ensure a satisfactory balance sheet.

It is further proposed that the financial independence of the Branch Councils should cease, and the income be all received by the General Council, which should administer the branches as such.

A further suggestion, often made before but never commending itself to the constituency, is to obtain power to levy an annual fee on registered practitioners. It is thought this would bring them more into touch with the Council. But that body is so much discredited that the profession has no desire to be in touch with it. First let the Council become representative of the practitioners and not of the corporations. Then it may argue that taxation and representation go together. Its present state is illustrated in the fact that the discussion on the finances was carried on *in camera*—the propriety of this being debated at considerable length and consequent expenditure.

The debate on the revolt of the London colleges was resumed on Saturday and continued again on Monday. The time thus occupied can scarcely be grudged, for the issue of the dispute is of the highest importance to the profession, and the subject is strictly within the duties of the Council. No one, I imagine, would wish the Council to act rashly on such a momentous issue. But it was well known that the colleges would repudiate registration of students, and I indicated to you in advance the arguments which were actually brought forward in defense of their action. It was hoped, however, that the Council would not climb down again, but would assert its authority and if necessary appeal to the Privy Council. Alas for the hope! Alas for its dignity! After all this discussion occupying so large a proportion of the session, the whole matter is referred to the education committee, and so shelved until next session, apparently in the hope of finding a *modus vivendi*. Vain hope! These two colleges have always put their own corporate interests before those of the profession. A chance of grasping extra fees has always been to them irresistible. What care they, then, about registration or raising the standard, if they can only open a side door to attract candidates? For the truth is that the fifth year is in danger—it is in fact referred to the committee—and all because two colleges want to count as the first year of the curriculum, the last year at a grammar school. If this is to be tolerated, of course all the other licensing bodies will follow suit.

The Council should have taken up the gauntlet thrown down and said, if you admit to your diplomas any one who has not been registered here as a student, we will not register as practitioners the recipients of such diplomas. It is said the colleges would then appeal to the courts to compel the Council to register them. Let them. At the worst, the Council would have done its duty to the public and established a claim to an amendment of its Act which has so long been sought for. But the colleges could not afford to carry defiance so far. If the Council warned students that they would not be registered as practitioners unless they had registered at the office at the commencement of the curriculum, how many would be enticed to enter the back door of the recalcitrant colleges?

But procrastination has always been the weakness of the Council, and the colleges could reckon on its reluctance to take decisive action. The evil results of this weakness were seen in the case of Dr. Irvine. Had the Council not postponed to another session its decision, it would not have had to endure the snub of Mr. Chamberlain in the House of Commons.

There was a report from the Committee on Medical Aid Associations, in which the formation of a Conciliation Board was referred to. But is conciliation the business of the Council, which is entrusted with penal powers as to registered practitioners, and has gone a little way—a very little way—in the direction of preventing their degradation by these aid associations? Conciliation at the best will mean compromise, and how can the Council act judicially after it has encouraged compromise? This difficulty was recognized by some councillors, and the reappointment of this committee was agreed to only on the understanding that it is for one year only.

The British Medical Association, which is working the conciliation move, was anxious to get a deputation heard, but the Council wisely declined. There was another deputation, one from Scotland, about the question of sale of poisons. There was actually a case under consideration of the Council in its judicial capacity, which in hearing this deputation would undoubtedly be referred to. It was postponed until after the decision of the case, and then an attempt was made to introduce the deputation on the general question. But the motion was defeated, the majority seeing clearly that such a course would be improper. But a great deal of time was wasted over the question of receiving or declining to receive the deputation. The incident reflects the inaptitude of the Council.

OUR PARIS LETTER.

(From our Special Correspondent.)

POZZI INAUGURATES A GYNECOLOGICAL COURSE AT THE BROCA HOSPITAL—LAW REGARDING THE DECLARATION OF VENEREAL AFFECTIONS IN WESTPHALIA—CURIOUS CASE OF AORTIC INSUFFICIENCY—BABINSKI'S RESEARCHES ON CYTO-DIAGNOSIS IN NERVOUS AFFECTIONS—TUFFIER'S LATEST ARTICLE—VOISIN AND WIDAL ON DIPHTHERIA TREATMENT—WALDECK-ROUSSEAU'S CIRCULAR TO HEALTH OFFICERS CRITICIZED SEVERELY.

PARIS, June 29.

On the 31st of last month Professor Pozzi delivered his first lecture on gynecology at the Broca Hospital. He gave in his speech a description of the manner in which a course of gynecology had at last been officially opened in Paris, the university of which was the latest to have carried out this idea. It is thanks to the initiative and the liberality of the Municipal Council of Paris that a professorship in this branch of medical science has been created. Dr. Pozzi spoke of his trips abroad in 1883, 1886, and 1887. He visited Hegar's service at Freiburg in Breisgau, and was much impressed by the superiority the Germans had acquired. Professor Pozzi also went to America later on and saw several of the leading gynecologists there. He tried to have a special course inaugurated in Paris, but failed to obtain the official sanction so necessary in France to any undertaking of this sort. Dr. Pozzi spoke of his treatise on gynecology which he began writing in 1888. He devoted two years to writing it, and left Paris to retire into the country in order to give all his time to it. He ended his discourse by giving a definition of gynecology and of the principles that should be followed by a surgeon, who should never operate until he had a complete history of the patient, had examined her thoroughly, and made sure that operative methods were the only means of obtaining a satisfactory result.

It seems that in the province of Arsuberg in Germany the physicians have been called upon to declare all

cases of venereal disease. Though this decree has been promulgated with the best intentions, it has been very much criticized by the medical and political press in Germany. Professional secrecy is rendered an illusion, for how can one imagine that anybody would care to go to consult a physician about any such disease if he knew that he would be likely to have his name appear in a medical report to the police authorities?

At a recent meeting of the Medical Society of the Hospitals Dr. Lannois showed a patient presenting a most curious form of aortic regurgitation. The patient, who had had syphilis, suffered for a long time from a pain in the region of the heart, when suddenly last October, after a violent emotion, he experienced a severe pain in the chest. He lost consciousness and fell down, and since then he has been able to hear distinctly a peculiar sound which can also be heard at a distance of twenty to twenty-five centimeters, and which seems to correspond to the second aortic sound. It is strident and throbbing.

Drs. Babinski and Nageotte made an interesting communication on the use of cytodiagnosis of the cephalorachidian liquid in nervous affections. They reported one hundred and twenty cases in which they had examined the number of lymph cells; and they found that there was lymphocytosis in all organic affections of the nervous system caused by syphilis, such as tabes and general paralysis. In all other forms, with the exception of tuberculous meningitis, no such symptom was to be observed. Cases of polyneuritis, cerebral tumors, hemiplegia, paraplegia, sciatica and myopathy were examined and no change found. In a recent case there was some hesitation between neurasthenia and general paralysis, and as the examination indicated lymphocytosis Dr. Babinski imagined it would prove a case of general paralysis.

Dr. Trosier showed two calculi, which had been found in the stools of two patients who had shown symptoms of intestinal obstruction, without ever having had bilious colic.

The discussion on medullar cocainization is not over yet, and Dr. Tuffier has published another long article on this subject. He had already read it to the Society of Surgery, and it was in part directly addressed to Professor Reclus. It seems that the reason why Tuffier has been supposed to have had six cases of death is that he published the case each time he described his technique. Tuffier upholds Corning as being the initiator of the method, and speaks rather sarcastically of the letters exchanged by Bier and Reclus, in which Bier speaks of Reclus as being the master in cocaine injections. Reclus had said that Tuffier was after all only the third to try this method, and Tuffier remarks that it was hardly necessary to insist upon this. Dr. Tuffier said that he preferred the open needle, because when a puncture is made, one can tell when the needle is inside the intrarachidian space on account of the escape of a few drops of liquid. If the liquid does not come on account of obstruction of the needle, the injection of a drop or two of the solution will free it. Tuffier could not understand why the puncture should be considered a difficult operation by surgeons when physicians perform it so often. He examined the cases of death and did not find that a single one can be conclusively attributed to cocaine.

At a meeting held on the 7th of June by the Medical Society of the Hospitals, Dr. Voisin spoke of the excellent results they had obtained in an epidemic of diphtheria at the Salpetrière by injecting antitoxic serum into all the patients exposed to it. There was only one fatal case, and nineteen patients were cured. The children over ten years old received twenty cubic centimeters and those under that age only ten. Dr. Widal, whose name is associated with orrho-diagnosis in typhoid fever, remarked that patients sometimes came into his service the fifth and even the seventh day of their illness without having been injected. In such cases sixty, eighty, and sometimes one hundred grams of serum were injected.

It would seem that M. Waldeck-Rousseau's circular to health officers does not suit the taste of all medical men, and a recent article published in one of the French medical papers shows that it is looked upon by some as being an attempt on the part of the civil authorities to dictate to physicians the treatment they should employ. This circular was an appeal to the health inspectors to recommend to the medical men of their district the early use of antidiphtheritic serum. The author of the article speaks of the law concerning autopsies which requires physicians to furnish their aid when called upon to do so, and sees in this recent circular the first attempt towards obliging physicians to adopt a uniform method of treating various ailments. In such a case all the freedom that a physician has had in establishing his own principles of treatment would disappear.

Book Reviews.

Points of Practical Interest in Gynecology. By H. Macnaughton-Jones, M. D., M. Ch., Q. U. I., Master of Obstetrics (honoris causa), Royal University of Ireland. New York: William Wood & Company, 1901.

This is an interesting work, composed of a number of chapters which are reprints of communications appearing serially in the *Edinburgh Medical Journal*. The chapters are ten in number and make interesting reading from the standpoint of the practical physician. The various divisions of the book are as follows: 1. Some points in gynecological asepsis; 2. Some pitfalls in gynecological diagnosis; 3. The therapeutics of disorders of menstruation; 4. Conservatism and its influence on operative technique; 5. Affections of the female genitalia as causal factors in the etiology of neuroses and insanity, and their special bearing on the operative treatment of the insane; 6. The indications for the operations of hysterectomy and myohysterectomy in myoma. In the appendix, the author deals of various minor subjects, the most important of which is Noble's method of closing cœliotomy wounds.

The Johns Hopkins Hospital Reports. Vol. VIII, Nos. 3–6. Baltimore, 1900.

This volume contains a number of interesting papers on typhoid fever.

In the domain of bacteriology and pathology the contributions are by Simon Flexner, "On Unusual Forms of Infection with the Typhoid Bacillus," by C. N. B. Camac on "The Gall-Bladder Complications of Typhoid Fever," by Wm. Osler "On the Hepatic Complications of Typhoid," by G. W. Dobbins on "Puerperal Infection with the Bacillus Typhosus," by J. F. Mitchell on "The Œsophageal Complications of Typhoid," and by N. B. Gwyn on "A Study of the Widal Reactions in 205 Cases of Typhoid Fever, with remarks on the disinfection of typhoid urines."

Typhoidal septicæmia, without the characteristic intestinal lesions, forms the basis of Flexner's article. Two new cases are added by the author to those already reported.

Camac says that the liver receives the typhoid bacilli from the alimentary tract in the beginning of the infection. This organ failing to dispose of the infection either because of an overwhelming force of bacilli or of their products or because of a previously diseased condition of the organ, throws its excess of work upon the spleen. In the event of still further infection the bacilli escape with the bile into the gall bladder during the intervals when that fluid is not being discharged into the duodenum. Once the liver and spleen are taxed to their utmost the escape of bacilli and their poisonous products into the system is inevitable, and the case is ripe for complications. Under hepatic complications of typhoid, Osler considers the focal necroses, jaundice, and abscess.

That a positive Widal reaction can be taken as conclusive of the presence of typhoid fever would seem to follow from Gwyn's studies. He obtained a positive reaction in 205 cases that clinically were diagnosed as typhoid.

The frequency of œsophageal ulcerations in typhoid fever, their etiological relation to the typhoid bacilli and the relation of such lesions to subsequent stricture of the œsophagus have been considered by J. F. Mitchell.

Contributions to phases of the symptomatology of the disease have been made by J. P. Lyon, "On Coincident Typhoid and Malarial Infections," by Osler, "On Hemiplegia in Typhoid," by Hamburger, "On Hemorrhagic Typhoid," by Emerson, "On a Case of Early Oculo-motor Paresis of the Left Eye occurring in a Case of Typhoid," by Young, on Chronic Cystitis due to the Typhoid Bacillus," and lastly an able contribution by Thayer "On the Blood of Typhoid Patients."

The articles of surgical interest have been prepared by Finney and Cushing and deal with the surgical treatment of perforating typhoidal ulceration.

The successful treatment of typhoidal perforaton of the intestine is of but comparatively recent date. It would appear, however, that the performance of abdominal section at the Johns Hopkins Hospital in typhoid patients is carried far beyond the limits of rationalism. The propriety of early surgical interference for the repair of ruptured ulcer with intestinal extravasation is no longer a matter for discussion, all are convinced of this, but the propriety of operative interference for a condition that does not exist and that may never occur in the so-called preperforative stage will hardly be accepted by the profession and much less by an intelligent laity. Likewise is promiscuous exploration of the abdominal cavity in typhoid patients to be decried. Merely because no fatal

result has followed in the few cases in which such exploration has been made, there is no reason for urging such practices as routine procedures. The exploratory operation should be reserved for those cases in which there are reasonable grounds for supposing the existence of a ruptured ulcer, and not used to establish a diagnosis, as Finney would have it. If employed as indicated above, neither will the surgeon be mortified if no perforation is found, nor will the laity complain that "needless operations" are performed. And further it is well to remember that the operation is not without its risks, for two to three per cent. of healthy individuals succumb to the simplest abdominal section.

In other respects the papers of Finney and Cushing afford us valuable information.

HUMAN PLACENTATION. An Account of the Changes in the Uterine Mucosa and in the Attached Fetal Structures during Pregnancy. By J. CLARENCE WEBSTER, B.A., M.D. (Edin.), F.R.C.P.E., F.R.S.E. Chicago: W. T. Keener & Co., 1901.

THE original and well-known researches in the department of embryology as worked out by Webster, formerly of Edinburgh, now of Chicago, are too well recognized to make this splendid volume as a continuation of the subject a stranger to those who are interested in the matter. The subject-matter in hand is taken up in divisions consisting of ten chapters, and in each we have both macro- and microscopical studies of all the material and embryonic structures as clearly and carefully exposed as modern scientific investigations allow. The book is a credit to both author and publishers, and it is a satisfaction to know that such work is being done in this country. The best chapter in the book is the tenth or last one, which treats of Phylogeny or the comparative study of the placenta.

UTERINE FIBROMYOMATA: Their Pathology, Diagnosis, and Treatment. By E. STANMORE BISHOP, F.R.C.S. Eng., President of the Manchester Clinical Society; Fellow of the British Gynecological Society; Honorary Surgeon of the Ancoats Hospital, Manchester, etc. Philadelphia: P. Blakiston's Son & Co., 1901.

THE volume before us is written by a well-known author on a subject with which he is fitted in many ways to deal. His subject partakes of the character of a specialty within a specialty, and the finer points of the question must of necessity be brought out in the fullest possible detail, and in this respect the book is everything that can be desired, and will certainly fill a long-felt want. Excellent as is the first part of the book, including the theoretical branches, what interests us most is the section on treatment. Under surgical treatment, our attention is directed to preparation for operation, the technique, and the post-operative treatment. The methods of the various operations, and there are many mainly differing in minor details, are given in tabulated form. Thus there are discussed vaginal, abdominal, and the combined hysterectomies. The inclination of the author appears to be to the abdominal method entirely or in modified form. But this is simply a matter of choice, of experience and habit in very many cases, for the man who is skilled in vaginal work will attack from this end and he who is an expert from above will almost always do the operation from the abdominal side. An interesting chapter as well as a rather disappointing one, is that on the electrical treatment of fibroids. The last chapter, one on final results, is one not usually found in text-books, and makes very interesting, though rather uncertain reading, since it is mainly based on statistical evidence. Yet we know that all patients who are operated upon, no matter how brilliant the immediate result, are not always cured from the standpoint of the clinician.

PULMONARY CONSUMPTION, PNEUMONIA, AND ALLIED DISEASES OF THE LUNGS: Their Etiology, Pathology, and Treatment, with a Chapter on Physical Diagnosis. By THOMAS J. MAYS, A.M., M.D. Professor of Diseases of the Chest in the Philadelphia Polyclinic; Visiting Physician to Rush Hospital for Consumption. New York: E. B. Treat & Co., 1901.

THE predominating influence of the nervous system in the etiology of pulmonary disease here finds an ardent advocate. Many statistics and histories are cited by the author in support of his claims and the patient research and wide reading which he has brought to bear as proof merit the highest praise. He claims that in a majority of cases consumption is primarily a neurosis, that the integrity of the nervous system is essential to preserve pulmonary health, and that the only remedial measures worthy of trial in pulmonary tuberculosis, act through the nervous system. He especially advocates injections of nitrate of silver over the vagi.

Besides these rather heterodox teachings, the book contains many valuable hints in treatment and [illegible] together with some startling proofs of the efficacy of the author's methods of benefiting this stubborn disease.

The latter part of the work treats of Pneumonia—again related to disorder in the nervous system—and acute and chronic bronchitis, asthma, and pleurisy.

HEALTH AND HYGIENE FOR THE HOUSEHOLD. By JOHN JOSEPH NUTT, B.L., M.D. Member of the American Medical Association, The New York State Medical Association, and the County Association. New York: The Abbey Press, 1901.

THIS book purports to instruct the laity concerning hygiene and the preservation of health. The instructions are good enough as far as they go, but the book is too small and too elementary to be of much service to any but the writer. Its utility in this regard may possibly be enhanced by a curious biographical sketch of the author signed by the publishers. In this we are told that the author's uncle founded a town near Chicago, and that the author himself organized a chapter of a Greek-letter society in college and is rapidly attaining prominence in his profession. The chapter on the choice of a family physician harmonizes with the biography.

THE PRACTICE OF CHARITY, INDIVIDUAL, ASSOCIATED, AND ORGANIZED. By EDWARD THOMAS DEVINE, Ph.D., General Secretary of the Charity Organization Society of the City of New York. New York: Lentilhon & Company, 1901.

THIS little guide for the charitable is from the pen of an expert in this most important sociological specialty, and is replete with instruction and valuable suggestions for those whose humane impulses to relieve the needy and suffering as well as for those, who as public officials or executive officers of church and other organizations, are brought face to face with the judicial and weighty problems of charitable relief.

DISEASES OF THE ANUS AND RECTUM. By D. H. GOODSALL, F.R.C.S. (Eng.), Senior Surgeon to St. Mark's Hospital for Fistula and other Diseases of the Rectum, &c., and W. ERNEST MILES, F.R.C.S. (Eng.), Surgeon (out-patients) to the Gordon Hospital for Diseases of the Rectum, &c. In Two Parts, Illustrated. Part I. London, New York and Bombay: Longmans, Green & Co., 1900.

THE authors of this work are offering us the results of their extended experience in the surgery of a limited region which is the seat of many pathological processes. This is the first section and if the second is as satisfactory we shall be in the possession of an excellent work of reference in this field of surgery. Anatomy, methods of examination, fissure, fistula, and all the varieties of hemorrhoids are discussed in the most modern and progressive way, and there are numerous illustrations which add very much to the value of the text. The authors take the ground that the radical procedures are really conservative in such conditions as fistula and hemorrhoids, and we think that most American surgeons will agree with these conclusions. They also believe that pulmonary tuberculosis is not a contraindication to operation in cases of ischio-rectal tuberculosis. All the various operative plans are described and clearly illustrated in many cases by unusually good photographic reproductions. We are glad to note the appearance of so useful a work.

INTRODUCTION TO THE DIFFERENTIAL DIAGNOSIS OF THE SEPARATE FORMS OF GALLSTONE DISEASE, based upon 433 Laparotomies for Gallstones. By PROFESSOR HANS KEHR, Halberstadt. Authorized Translation by WILLIAM W. SEYMOUR, A.B., M.D., &c. With an Introduction by Professor Kehr. Philadelphia: P. Blakiston's Son & Co., 1901.

THIS translation gives to English readers the benefits of an intimate knowledge of a very extensive series of cases of gall-bladder disease. Any one who has cared for more than four hundred cases of the same class may speak with authority, and consequently Prof. Kehr's opinions are worth recording. The present work goes extensively into the etiology, pathology, symptomatology, and treatment of the various conditions brought about by calculi and, barring the inevitable Teutonic prolixity, its author has been successful in giving us a comprehensive sketch of the subject. The translator has not been very successful in transferring the German idiom to good English and he would have done well to have suppressed most of the description of post-operative detail. However there is much of value and interest in the work, and its subject is of great importance.

DEUTSCHE MEDICIN IM NEUNZEHNTEN JAHRHUNDERT.

THIS is a series of interesting reprints from the *Klinische Rundschau*. Most of the papers are by well-known men upon subjects of general interest relating to the history of medicine.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

TWENTY-THIRD ANNUAL MEETING,

Held at New Haven, Conn., May 27, 28, and 29, 1901.

HENRY L. SWAIN, M.D., OF NEW HAVEN, PRESIDENT.

First Day—Monday, May 27.

THE meeting was held in Dwight Hall, Yale University, and President Arthur T. Hadley, of Yale, delivered the address of welcome.

Laryngology and its Place in Medical Education.—DR. HENRY L. SWAIN began his address by speaking of the radical changes that had taken place in medical education since the establishment of the Association in 1878, and dwelt upon the question of how much time should be devoted to the study of special branches. The suggestion was made that more latitude should be given to the individual, that a minimum time only should be prescribed, and that the student should be given to understand that he must pass a severe examination before graduation, and that if he fails on the first attempt the second examination will be harder. It seemed to the speaker unwise to compel a student, who had chosen a certain special field, to spend many months in the exhaustive study of other special branches. The faculty should act as an advisory body in such matters, and should demand a certain knowledge of the essential and fundamental branches. In this way, the student who had not made any choice of a specialty would still find that he must receive ample instruction and training before being allowed to graduate. While it might be debatable at the present time whether or not the didactic lecture had outlived its usefulness, it should be remembered that the very plethora of our knowledge makes it almost necessary for the teacher to make a suitable selection of the pabulum to be served out to the student. The rapid changes in our knowledge emphasize the need of such instruction, and make it incumbent upon these teachers to make their lectures bright, crisp, interesting, and thoroughly up to date.

A Leaf from the Ancient History of the Anatomy of Nasal Catarrh.—DR. JONATHAN WRIGHT, of Brooklyn, N. Y., read a paper with this title. He said that the records of the existence of catarrh are coeval with the human race. Nasal anatomy had certainly been very crude in ancient times, for, in a book supposed to have been published about 1500 B. C., the statement is made that there are four vessels in the nose, two for blood and two for mucus. Herodotus described a practice of burning the veins of the brow at the age of four years with the object of preventing in after life "a flow of rheum," yet he would be surprised, if alive to-day, to know that some practitioners have transferred this practice to the tissues within, and are claiming wonderful curative results from such treatment. Hippocrates must have had some knowledge of the relation of nasal catarrh to stomach disorders, for, in a book attributed to him, the statement appears that "the bellies are subject to frequent disorders owing to the phlegm running down from the nose." It was a common belief in olden times that the nose was the cloaca of the brain. Galen says that each nostril is divided into two portions, one leading to the mouth and the other to the brain. He taught that the thicker discharges escape through the "sieve-like bones," while the more vaporous ones escape upward through the sutures. Theophilus, in the seventh century, recognized the olfactory nerves as such. Nine hundred years later, the professor of anatomy at Bologna, who did a thriving business curing the clergy of syphilis by means of his new-fangled mercurial treatment, denied that fluids pass through the ethmoidal plate. Willis and his contemporaries elaborated the error that the nerves are hollow and convey fluids. Schneider taught that the catarrhal discharges come from the nasal mucous membrane itself, and not from the brain, but he did not mention the mucous glands by name at all.

Asymmetry of the Nasal Cavities.—DR. A. COOLIDGE, Jr., of Boston, read this paper. He said that the greatest development of hypertrophy was on that side which is most open. He had not been able to find satisfactory proofs of the relation of the turbinates to deflections of the septum. In many of the reported cases the turbinates in the obstructed cavities were normal. In his own case the deflection had been towards the unobstructed side. It had been suggested that deviation of the septum was secondary to hypertrophy of the turbinates, but there were many reasons for rejecting this view. Others claimed that neither condition is the result of the other, but that both are the result of a condition of general asymmetry. There seemed to be no doubt that Nature has some method by which the air-carrying capacity of the two sides may be kept approximately equal. As one function of the nose was to transmit air, it seemed reasonable to expect the bones to adapt themselves to this function; hence, if asymmetry were present in one structure, asymmetry in neighboring structures should be looked upon as physiological rather than pathological. A turbinate body should be judged by the distance between it and the septum, and not by its absolute size. The ethmoid and turbinate bones are especially adapted for effecting a readjustment and maintaining the physiological balance.

DR. ARTHUR A. BLISS, of Philadelphia, called attention to the part played by the development of the palatal processes of the superior maxilla in the production of asymmetry of the nasal chambers. The upward thrust of these processes during development must press upon the nasal septum, causing it to be pressed upward against the base of the skull.

DR. EMIL MAYER, of New York, said that nearly all children having deviations of the cartilaginous septa develop sooner or later obstruction of the posterior nares, and the absence of a sufficient current of air seemed to him sufficient to explain the redundancy of the turbinated body on the deflected side. If one made it a rule to pay no attention to the size of the turbinates until after deviations of the cartilaginous septum had been corrected it would rarely be found necessary to do anything for these turbinates.

DR. E. L. SHURLEY, of Detroit, divided these cases of nasal asymmetry into two classes, viz.: (1) Those which the asymmetry is post-natal and accidental, due to pathological changes, and (2) those in which it is evolutionary. An important factor, though one often overlooked, was the frequency of difficult labor among the higher classes, and the modern tendency to use the obstetric forceps with but slight justification.

DR. D. BRYSON DELAVAN, of New York, was of the opinion that deficient air supply was the fundamental cause of nasal asymmetry, and that if these persons could be subjected early enough in life to treatment directed to securing the proper admission of air the abnormalities so commonly observed would be prevented.

DR. H. L. SWAIN, of New Haven, remarked that it would not do to ignore wholly the forces at work outside of the nose; the tremendous differences in nasal cavaties and heads were suggestive.

The Supralabial Operation (Dr. Harrison Allen's) for Deflection of the Nasal Septum.—DR. ARTHUR AMES BLISS was the author of this paper. He said that where no overhang exists, and the extreme point of deflection extends above the anterior nasal spine, the anterior part of the vomer was often also deflected, usually

in both a vertical and horizontal plane. The large free area of the triangular cartilage lay just above the anterior nasal spine. Any force acting from without which tended to twist this cartilage in the vertical plane would produce a twisting of the anterior nasal spine, and, to a much less extent, of the anterior part of the vomer. Dr. Harrison Allen's operation, the result of exhaustive clinical and anatomical research, consists in the division through, or immediately over, the maxillary crest, thus making the anterior part of the septum freely movable. A small sharp bistoury should be used to divide the frænum of the upper lip. A small strong chisel is then passed through this wound, and carefully pushed upward in the median line until the maxillary crest is reached. Its shank is then raised so that the cutting surface points directly against this crest, facing inward and very slightly downward or upward, according to the height of the vestibular floor in its relation to the floor of the nose. A few light blows of a hammer drive the chisel through the anterior nasal spine as far as the nasopalatine foramen. If the operator has been careful to direct the chisel so as to completely divide the maxillary crest, a finger introduced into the occluded nostril will at once force the septum over as far as desired. A rubber tube splint should now be placed in what had been the occluded nostril, and should be retained about as long as in the Asch operation. A cold water dressing should be kept on the lip and across the bridge of the nose for a day or two, the patient being in bed, and the parts should be cleansed with an alkaline spray. The operation should be done under light etherization. Hemorrhage is slight, and if the cold water dressing is used there will be only moderate swelling. Any ridges existing along the line of attachment between the vomer and triangular cartilage can be removed at the time of the septal replacement, or subsequently under cocain anæsthesia. This operation, though applicable to a large number of cases, and one which had given him uniformly satisfactory results, was almost unknown to the profession.

A Radiographic Study.—Dr. Henry L. Wagner, of San Francisco, exhibited a radiograph which had served him well in the removal of a metallic disk which had been impacted in the œsophagus of a child of five years. The interesting point was that this radiograph had not exaggerated, as had been supposed, the size of the body.

Dr. J. Edwin Rhodes, of Chicago, reported a case in which, although the œsophageal forceps did not seem to reach a penny that had lodged in the œsophagus of a little child, the object had been seized with the forceps under the guidance of the X-rays combined with the use of the fluoroscope.

Dr. D. Bryson Delavan reported a case in which a radiograph had enabled Dr. W. T. Bull and himself to locate and extract a five-cent piece from the throat of a little baby.

Dr. Jonathan Wright, of Brooklyn, called attention to a case in which a Brooklyn surgeon, in operating for the removal of a foreign body had followed with the point of the forceps the image of the foreign body, as shown in the fluoroscope at the time of operation.

Dr. A. W. de Roaldes, of New Orleans, urged the more general use of the œsophagoscope, an instrument often of great value, because it enables the surgeon to remove a foreign body under the guidance of the eye.

Dr. Wagner, in closing the discussion, remarked that it was important to know the measurements of the œsophagus in order to determine the possibility of the foreign body having passed through.

Epipharyngeal Lymphosarcoma.—Dr. Wagner also reported a case in which such a tumor had occurred in a boy.

Chancre of the Tonsil.—Dr. J. Edwin Rhodes, of Chicago, presented a communication on this subject. He said that, in collecting statistics upon this subject, he had been impressed with the frequency of the innocent origin of this form of syphilis. Tongue spatulas, dental instruments, and various household utensils were common media of contagion. The patch on the tonsil consists of a dirty, superficial ulcer, usually oval or circular. The submaxillary gland is always enlarged, and pain and general malaise may be associated with the development of this lesion. As a result of the mixed infection the process may assume a general phagadenic character; The chancre usually disappears in from four to six weeks. Several illustrative cases were reported, together with a table of thirty-one cases of chancre of the tonsil hitherto unreported. Most of these had been furnished him by members of this Association. His conclusions were as follows: (1) Chancre of the tonsil is often unrecognized; (2) an enlarged and indurated tonsil with a superficial ulcer upon its surface, accompanied by enlargement and induration of the contiguous submaxillary gland, and unchanged by a prolonged course of treatment, renders the diagnosis of chancre probable; (3) the character of the chancre depends upon the original condition of the tonsil and the coincidence of mixed infection. (4) a certain diagnosis cannot usually be made until the development of the general eruption; (5) the disease is no more severe than with chancre elsewhere; (6) it is produced by direct contact of the virus; (7) it should serve as a warning to use the greatest care in the sterilization of instruments, particularly in the case of dental instruments which are usually cleansed only by washing, and (8) the patient should be most carefully instructed as to the attendant dangers.

Drs. J. H. Bryan and J. W. Farlow reported cases to emphasize the author's statement regarding the difficulty experienced in recognizing the nature of this lesion of the tonsil.

Dr. W. K. Simpson expressed surprise that the author had succeeeded in collecting so many cases, when it was almost unknown in the large clinics of New York.

Dr. E. Mayer said that certain experiments had shown that the virus withstands ordinary sterilization by heat, some other method of sterilizing instruments would seem desirable.

Dr. D. Bryson Delavan said that he had seen several cases of chancre of the tonsil, and in all of them the onset of the disease had been unusually severe. He hoped the profession would use its best efforts to teach the laity that syphilis is an infectious disease.

Dr. George A. Leland, of Boston, said that although the statement had been made in the paper that chancre of the tonsil has a pearly color, in a case occuring in his own practice the tonsil had been of a bright red. The opalescent appearance he had only observed in secondary infections of the tonsil.

Serous Disease of the Maxillary Antrum, with a Report of Two Cases.—Dr. William E. Casselberry, of Chicago, read this paper. He said that chronic catarrhal sinusitis might result in polyps, cysts, osteophytes, and serous collections. The first three might also exist in conjunction with suppurative sinusitis. The term mucocele, while sometimes applied to serous collections, was more particularly applied when the contained material is mucoid or semi-solid. Several modern authors were disposed to retain the term hydrops as a recognition of a non-cystic serous exudation. After a review of the literature, the author reported two cases, one of acute sinusitis with retained muco-serous secretion, and one of the chronic serous disease. In the first case a few months after some recurrent polypi had been removed, the patient had returned with an acute cold, and on aspiration serous fluid had been withdrawn which was devoid of cholesterin crystals but contained lymph corpuscles and a large quantity of albumin. This had been evacuated and the cavity curetted. Recovery thereafter had been uneventful and permanent. Puncture had been made under aseptic precautions,

and apparently it had nothing to do with the subsequent pus formation, particularly as no such result followed numerous punctures in the second case. The second case was that of a woman of sixty-two, who had had polyps removed from time to time. Resection of the middle turbinate had been done by the author's method after serous fluid had been withdrawn by aspiration of the right antrum. Six aspirations in all had been made from the right antrum, and serous fluid withdrawn each time, but there had only been a few drops the last time. Natural drainage of the maxillary sinus had been restored by the removal of obstruction from the nasal surfaces. Chemical tests showed the presence in the fluid of serum albumin, but not over one-eighth per cent., and apparently there was also a trace of mucin. The first bacteriological examintation showed only large colonies of colon bacilli, the second a few micro-organisms but no specific bacteria. Inoculation experiments on animals were negative. Dr. Casselberry said that there were no signs about the gums pointing to dentigerous cysts, and if there had been a cyst on the left side it must have ceased to refill after one respiration. The fluid resembled a cystic fluid except that it did not contain cholesterin crystals. In these cases the transillumination test had not been decisive, there being on the affected side no shadow, but only an impairment of translucency. The appropriate treatment of such cases was indicated by the results achieved in his second case.

Empyema of the Antrum of Highmore in Young Infants.—Dr. Emil Mayer, of New York, was the author of this paper. He said that the apparent rarity of this affection, judging from the few cases on record, due, in all probability to the difficulties in the way of diagnosis, the remarkable unanimity of the symptoms in the cases diagnosed as such, the original methods employed for their cure and the all too brief mention or complete omission in most text-books, should make the study of empyema of the antrum of Highmore in young infants of increasing interest to the rhinologist. Not more than a dozen cases were to be found in literature. The writer presented a case of his own which occurred in a child aged two and one-half years, in whom the general symptoms noted had been eversion of the right lower lid, fistulous opening in the cheek on the right side, from which pus exuded, and a most penetrating odor from the same side of the nose. The child had been well until six weeks before having been seen, when an attack of scarlet fever and pneumonia had occurred. Two weeks later there had been a very severe nasal diphtheria, and subsequently an abscess had formed on the cheek. This had been incised and had resulted in a fistulous opening. At the time of the examination a small probe entered the fistulous opening and revealed the presence of a large cavity in a downward direction and gave the sensation of necrotic bone. Examination of the pus showed streptococci and staphylococci in abundance; but no Klebs-Loeffler or tubercle bacilli were found. The diagnosis of an abscess of the antrum of Highmore, with diphtheritic infection, had been made, this had been operated upon and cured. Another case was presented by the writer, the main facts of which had been communicated to him by Dr. W. B. Platt, of Baltimore. Six other cases were to be found in literature, all of them due to infection. The interesting question had been raised regarding these cases as to whether they are simply carious conditions, *i. e.*, tuberculous, or an osteomyelitis. Reports of bacteriological examinations had been made by various observers, notably by Moritz Wolff, of Germany, and Richard Mills Pierce, of this country. The writer's conclusion was that it had been established beyond doubt that empyema of the antrum of Highmore in young children is not merely caries, or tuberculosis, or possibly an osteomyelitis, but as distinct an affection as in later life. That so few cases had been noted in the living was in all probability due to the fact that the mortality is greatest when this complication occurs, and also because in the very young the presence of localized pain is so difficult to establish. In all the reported cases the symptoms had been the same, viz., fistula under the eye, usually discharging pus, ectropion, one-sided purulent discharge from the nose, with foul odor, and eroded bone. Careful observation, especially in nasal diphtheria when the bacilli are present, might enable one to discover these cases and by prompt attention, bring about recovery. Incision, curettage and thorough drainage would be followed by complete cure in the vast majority of cases.

Abscess of the Frontal, Ethmoidal, and both Sphenoidal Sinuses, with extensive Necrosis of these Bones, Complicated by Adenoma of the Posterior Ethmoidal and Sphenoidal Regions.—Dr. J. H. Bryan, of Washington, D. C., reported this case. An external incision had been made, a flap consisting of the soft parts and the periosteum raised, and a button of bone removed just above the supraorbital ridge. The sinus was found filled with pus and granulation tissue, and the probe detected disease of the bony walls. A free communication between the sinus and the nose was left. The parts were cleansed by irrigation, and the wound united and sealed with collodion. At the end of a month the patient had sufficiently recovered to go to her country home and she no longer suffered from headaches. That summer she had contracted a severe cold in the head, and this had been attended by redness and swelling, owing to interference with drainage through the nose. Her family physician had made an incision into this swelling, and evacuated pus. This had given some relief, but pus continued to be discharged when he had next seen her in the autumn. Daily antiseptic irrigations of the sinus and wick drainage were followed for several months without benefit, and then it became necessary to open the sinus again as before. The sinus was found filled with granulation tissue with an accumulation of pus in the most dependent part. There also was extensive disease of the ethmoid. As much as possible of the diseased tissue was removed. One month later she was suddenly seized with violent frontal headache, which was partially relieved by the evacuation of some retained secretion from the ethmoid cells. Iodide of potassium was given to the point of tolerance, but without result. A third operation was required for threatening orbital abscess, and after this she suffered to some some from vertigo and diplopia. Four months later there appeared a rather firm growth proceeding from the posterior ethmoidal and sphenoidal regions. When the sphenoidal sinus was opened some foul pus was evacuated. At present, both sphenoidal sinuses are still the seat of suppuration. The rapid development of this growth made it impossible to maintain free drainage. Bacteriological examination of the discharge had been made on two occasions, but only a few staphylococci were found. An unfavorable termination of the case seemed almost certain.

Second Day—Tuesday, May 28.

Reflex Epilepsy from Nasal Disease Successfully Treated by the Removal of the Latter.—Dr. John O. Roe, of Rochester, was the author of this paper. He said that Brown-Sequard had shown that epilepsy could be produced by artificial irritation of the peripheral nerves in almost any part of the body. The pathology of epilepsy was as yet an unwritten chapter in the history of the disease. Several cases were then narrated, of which the following may be taken as a fair illustration: A girl of eleven years had had prolonged nasal obstruction, and had suffered from severe epileptic seizures since the age of six years. She had been born asphyxiated after a difficult labor. At times she had had

as many as ten to twenty-four seizures a day. Each summer she had had a long attack of hay fever, and had long suffered from gastro-intestinal catarrh. The attacks had been steadily increasing in both frequency and severity up to the time of her coming under his observation in December, 1900. Both nasal cavities were almost completely occluded and the pharynx was filled with adenoids. The latter were extirpated and the nasal obstruction relieved, and during the past three months it was evident to every one that her general condition was greatly improved. According to the record kept by the family this child had had about one thousand convulsions a year for a period of five years.

Dr. Arthur A. Bliss, of Philadelphia, said that while the general practitioner and even the neurologist might perhaps hesitate to receive the statement that epilepsy may have such reflex origin it was not so inconceivable when one recalled the intimate relations between the nose, the cervical sympathetic, and the circulation.

Dr. J. N. Mackenzie, of Baltimore, spoke of the subject from a historical point of view, and Drs. A. W. Watson and A. W. Roaldes cited illustrative cases.

General Anæsthesia in Operations upon the Nose and Throat.—This was the subject for special discussion.

A.-C.-E. Mixture and Ethyl Bromide for Adenoid Operations.—Dr. R. W. Gleitsmann, of New York, opened the discussion with a purely clinical contribution to this special part of the subject. He said that for several years he had used the A.-C.-E. mixture and had been fortunate enough to have no ill results from it. It had been his habit to administer the mixture to a child lying on a couch, and then to slowly raise the little one in a chair to the upright position, in which position he operated. This had been his practice for years, and it was his rule to operate on adenoid cases in his office. He had used the ethyl bromide since 1864. Dr. E. Mayer had reported his experience in 250 cases, claiming that it was harmless in quantities of ten to fifteen grammes, that anæsthesia was quickly induced, that the anæsthesia lasted from a minute and a half to two minutes and a half, and that it produced no unpleasant after effects. The drug should be perfectly pure. It was not suitable for maintaining a prolonged anæsthesia. The majority of operators begin by pouring 10 grm. upon a mask, and use altogether 30 or 40 grm. He had used ethyl bromide in at least 500 cases, and in only two instances had it been necessary to interrupt the anæsthetic because of unpleasant symptoms. His mode of operating was as follows: one assistant held the child and the other gave the ethyl bromide and later held the head. It was better to operate in a darkened room with artificial illumination. He used a mask which almost completely excluded the air from the nose and mouth. He used a forceps first and afterwards a curette in removing the adenoids. He passed the instrument into the pharynx four or five times and the patient's head was quickly lowered during the operation to favor the outflow of blood. He had never witnessed the inflow of blood into the larynx.

Nitrous Oxide, Chloroform, and Ether.—Dr. F. E. Hopkins, of Springfield, Mass., discussed this topic in the absence of Dr. T. R. French, who had been expected to take up this subject. Ether, he said, was eminently safe, and nitrous oxide was agreeable to the patient. By beginning with nitrous oxide and following this with ether one obtains a most happy combination. The more common use of nitrous oxide in England might be due to a reaction from chloroform. The time of unconsciousness would seem to be too short with nitrous oxide gas for a thorough clearing of the pharynx in some cases. This duration of the anæsthesia was especially short in children, and was always uncertain; moreover if hemorrhage were going on in the larynx it was dangerous to reapply the anæsthetic. Deaths from chloroform often occur [illegible] and of anæsthesia. For [illegible] used in his practice [illegible] exceptionally careful and [illegible] perienced in the use of chloroform. At the end of a year, a child had suddenly died in the [illegible] then chloroform had not been used in his practice. When chloroform was used it should be replaced by ether during the operation. Ether was the only anæsthetic with which he had had any unsatisfactory experience, while there had occasionally been untoward symptoms in these cases, unlike those occurring with chloroform, which seem to be so utterly hopeless from the very onset of the dangerous symptoms. In spite of the element of safety associated with ether there were the disadvantages of the patient's resistance at the beginning and the distressing nausea afterward. The administration of ether by the rectum had been used as far back as 1847, and by some writers had been considered very useful. Severe meteorism, diarrhœa, and even melæna had been reported after rectal etherization. The use of nitrous oxide gas preliminary to ether had been found an exceedingly pleasant and effective way of producing anæsthesia.

Dr. J. N. Mackenzie, of Baltimore, said that he had been using ethyl bromide in private and hospital practice since 1887, having been led to do so by the writings of his friend, Dr. J. Chisholm, of Baltimore, who deserved great credit for having called renewed attention to this anæsthetic. He had never had an accident, but did not think it was free from danger unless given without any air and after the use of a stimulant.

Dr. W. E. Casselberry, of Chicago, said that for the last fifteen years his usual mode of operating in adenoids alone, or on adenoids and hypertrophied tonsils, had been to administer first a few drops of A.-C.-E. mixture, to avoid the unpleasant stage of ether and to follow this by ether, and use the latter throughout the period of anæsthesia. He had used bromide of ethyl quite largely in office and dispensary practice, especially in those cases in which only adenoids or hypertrophied tonsils were to be removed. It was, however, somewhat unreliable, sometimes failing to anæsthetize an excitable child. On this account, he had not cared to use it in private practice. Nitrous oxide gas is the safest of anæsthetics for brief operations. Recently he had followed this gas by the use of ether to prolong the anæsthesia. He had not been satisfied with the closed inhaler ordinarily used in conjunction with this method, and preferred, when the anæsthesia was nearly complete, to substitute for it the open cone, made with towel and paper, and having one end loosely closed with cotton. At the time of the change to the open cone there was apt to be a momentary lull in the respiration, but this had no significance. After this change of the inhaler ether is given in the ordinary way to the conclusion of the operation. In his own cases it had usually required five or ten minutes for the combined operation on the tonsils and adenoids.

Dr. E. Mayer, of New York, said that when gas and ether were properly given no cyanosis either appeared. He preferred this method of anæsthesia for all cases in his private practice, as the operation could be done without undue haste and yet the patient would regain consciousness very quickly. Attention had been recently directed to the value of adrenal preparations as a means of securing reanimation in cases of collapse occurring in connection with the use of anæsthetics.

Dr. A. W. de Roaldes said that the enthusiasm that he had evinced ten years ago when reporting his first cases anæsthetized by the use of bromide of ethyl had not abated, but he could say that in the five thousand cases he had met with unpleasant effects only two or three times. If bromide of ethyl were used

properly the child would awaken just exactly at the moment when its co-operation was desired for the removal of blood. This anæsthetic was not an irritant to the nasal mucous membrane and did not depress the heart after the manner of choloroform. Its action was a little less fugitive than that of nitrous oxide. It was not inflammable, and hence could be used with perfect safety near a flame. It was most important to use a pure preparation and one that had been preserved in a sealed glass tube. For adenoid or tonsil operations there was no necessity for producing deep anæsthesia.

Dr. W. K. Simpson, of New York, said that the number of cases in which he found it unnecessary to use an anæsthetic for these operations was steadily increasing. He saw no reason for ever using an anæsthetic for the removal of the tonsils. He was confident that the tonsils could be removed better without an anæsthetic than with one.

Dr. D. B. Delavan deplored the position taken by the last speaker. It was too late, he said, to speak against the use of anæsthetics in these operations, for there was too much testimony in their favor.

Dr. Henry L. Wagner, of San Francisco, said that a pure preparation of bromide of ethyl has an ethereal or strawberry odor, whereas an impure article usually had an odor somewhat resembling that of an onion. He had had a large experience with the rectal administration of ether, and had found it a most admirable method, and one well adapted for operations about the face, nose and throat.

The Tonsils from a Purely Clinical Point of View.—Dr. F. H. Bosworth, of New York, was the author of this paper. He said that he knew of no work in anatomy or physiology which describes the masses at the root of the tongue in the same way as the faucial tonsils are described, probably because the latter assume such prominence in disease of this region. The trend of modern opinion seemed to be distinctly in favor of considering the faucial tonsils as organs whose function is to guard the system against the entrance of noxious germs. It was difficult to understand why nature should place these sponge-like bodies in the throat, for their structure was such as to make them admirable traps for germs. He thought a more tenable view was that the faucial tonsils do not exist in a perfectly normal throat. He had made this statement in the course of a discussion in London twenty years ago, and it had been received with jeering skepticism, yet after all these years of further experience he felt still inclined to make this statement, although not with perfect positiveness. He thought it was a matter of general clinical observation that partial extirpation of the tonsil leaves the throat often in a worse state than before. During the past thirty years he had insisted upon the use of an anæsthetic in the tonsil operation, and his preference had been for chloroform. This anæsthetic should be administered on a handkerchief, with the child in a sitting posture until complete removal of all sensation of pain, and then one tonsil should be removed. In his very large clinical experience of twenty-five years he had not seen a single dangerous complication or anything which seemed to indicate the alleged dangerous tendencies of chloroform. For the past ten years he had not cut tonsils with the tonsillotome, finding that the cold wire snare adapts itself so thoroughly to the tonsil as to leave, in his opinion, nothing to be desired. If the whole mass were not removed at the first operation it was a simple matter to repeat it until the pillars fall into their natural position. Troublesome hemorrhage was not often met with in children when the knife was used, but severe hemorrhage should always be anticipated in operating with the knife upon adults. The cold wire snare avoids this complication.

The Histology of the Retrograde Changes in the Faucial Tonsils of the Adult—Dr. J. L. Goodale, of Boston, read this paper. He had undertaken the study upon a series of tonsils removed at autopsy along with some of the surrounding tissue. The mucous membrane covering the tonsil appeared intact, and unusually thick. The mucous membrane of the crypts sometimes resembled that of the young tonsil, while in other cases it was more like that of the free surface of the tonsil in its structure. The amount of lymphoid tissue in proportion to the connective tissue was always relatively less than in early life. This subject of the structure of the tonsil was illustrated by the presentation of colored drawings and numerous photomicrographs. The first retrograde change observed in the process of sclerosis was a shrinkage of the endothelial reticulum. In an atrophied tonsil the follicles near the crypts maintain a greater activity than those more remote. The retrograde changes begin in the trabeculæ.

Dr. J. O. Roe said that he fully agreed with Dr. Bosworth regarding the tonsil being an accompaniment of some abnormal state of the throat. He believed there was no diseased structure in the upper air passages which caused more disturbance, particularly in children, than the tonsils. They simply invite the lodgment of disease germs and infection of the system.

Dr. A. A. Bliss did not think that the tonsils should be entirely eradicated in every case. If all of the tonsil were to be removed, the snare was probably the best instrument, but for the partial removal of the tonsil there was a choice of instruments. In total excision there was some risk from cutting of the tonsillar artery, though ordinarily the bleeding comes from the ascending branch of the palatine artery.

Dr. Robert C. Myles, of New York, thought Dr Bosworth's position was being more and more generally accepted as correct. For operating on the tonsil with the cold wire snare, general anæsthesia was required. Where the tonsils were pedunculated the guillotine could be easily used under cocain anæsthesia, but a very strong solution of cocain must be used and must be kept in contact with the parts for a long time before the operation.

Dr. Clarence C. Rice, of New York, said that it was quite sufficient to excise the non-inflammatory tonsils of the child to the level of the pillars of the fauces, using the tonsillotome. The large inflammatory tonsils of adults should be extirpated with the galvano-cautery.

Dr. Price Brown, of Toronto, Canada, said that in a practice of thirty years he had never seen a fatal case from chloroform anaesthesia, and hence he doubted the propriety of his changing to another anæsthetic. It was his practice to have his patient recumbent, and to turn him quickly on the side to favor the escape of blood.

Third Day—Wednesday, May 29.

Vocal Nodules.—Dr. C. H. Knight, of New York, was the author of this communication. He said that the term "singers' nodules" was by no means altogether appropriate. In the opinion of Chiari mucous glands are seldom concerned in the constitution of these nodules. They are more common in women than in men, and are not rare in children. The relation of vocal nodules to tuberculosis was still undetermined. In his own experience this relation had been purely accidental. The author then narrated a case which had recently come under his observation. The patient was a lady who rarely sings, but who is a good deal of a talker. There was a good deal of chronic laryngitis with hyperplasia of the lymphoid tissue at the base of the tongue. Simple local treatment produced improvement, but some months later, after having caught cold, this lady sang in church under circumstances which excited her emotions. An examination at this time showed the larynx to be very irritable. The treatment consisted in the use of daily sprays and of a solution of alumnol, twenty grains to the ounce. After a time, on his advice, she had taken a course of vocal gymnastics under a professional voice trainer. The

treatment consisted, in the first place, in teaching a correct method of breathing, but was, in the main a "rest cure" hence the common expression "vocal massage" was evidently a misnomer as regards this treatment. In consideration of the fact that in cases of malignant disease of the larynx so much benefit sometimes follows ligation of the arteries supplying the part, he had been led to endeavor to produce an ischæmia of the larynx in this case by the use of suprarenal extract. Accordingly daily instillations of a 1 5,000 solution of an adrenal preparation had been made for three weeks. This treatment, together with the vocal training had effected considerable improvement, and the nodule was evidently shrinking. In his opinion, misuse of the voice was a much more probable etiological factor than overuse of the voice, but it was evident that a throaty voice could not be the only element otherwise these cases would be far more common. One would naturally expect vocal nodules to be developed in those using the speaking voice a good deal rather than in connection with the singing voice because of the comparatively short range of the former. The author suggested the possibility of these nodules arising from overuse of certain muscle bundles, thereby causing hyperæmia and hyperplasia, or there might occur under these conditions a minute localized hemorrhage. A theory that these nodules result from attrition of the vocal cords seemed to him untenable because a space must always exist in order to permit the blast of air to escape. Moreover these nodules, as in his own case, do not always appear upon the margin of the cord.

Dr. C. C. Rice said that the cases of vocal nodules that he had seen had been uniformly in professional singers, had almost invariably in "light opera" singers as distinguished from the "grand opera" singers. This might be explained by the fact that the grand opera singers use their voices much less frequently and also more skilfully. He believed these nodules were rather the result of overuse than misuse of, the singing voice. He was inclined to think that insisting upon proper vocalization was a better means of reducing these nodules than total rest. He had lately had a few cases do well under the topical use of chromic acid, and it had been reassuring to note how perfect had been the repair of the vocal cord.

Dr. W. K. Simpson was inclined to think that the term "vocal nodule" was applied to a number of lesions in the larynx, some of them quite fugitive ones. Hypertrophies at the base of the tongue certainly led to overuse of the voice; indeed, when there was much lymphoid tissue in this situation, he hardly knew of anything which would so improve a singer's voice as its removal. Such an operation not only improves the quality of the voice, but enables the singer to use it with much less effort. These nodules were apt to appear in those whose general health was below the standard.

Dr. H. L. Wagner said that his experience showed plainly that these nodules undoubtedly occur in others than singers, and often in those who are anæmic. He was satisfied that overuse of the voice meant misuse, because, when the voice is overused, certain muscles are used which would not otherwise be brought into play.

Dr. J. W. Farlow, of Boston, said that he had seen these nodules more commonly in non-singers than in singers, and even had observed them in a child of nine years. Anything which tends to make a throaty voice, or to make the throat expel some resisting mass, is apt to lead to the development of these nodes.

A Study of the Proper Application of Intubation in Chronic Stenosis of the Larynx.—Dr. W. K. Simpson, of New York, read a paper on this subject, in which he considered only chronic laryngeal stenosis arising independently of syphilis. He divided the cases into three groups, viz.: (1) Cases of gradually developed stenosis, and not necessarily demanding operation; (2) cases of acute stenosis demanding prompt operative intervention, and (3) cases in which it is desirable to interfere in order to do away with the use of the tracheal canula. An accurate diagnosis was a prerequisite to the treatment, and under this head was included a knowledge of the location of the swelling, the density of the tissue, whether or not ulceration is present, and whether the condition of the patient will allow of the necessary laryngoscopic examination. If such an examination could not be made prior to intubation, then this operation should give way to tracheotomy, with the idea of perhaps subsequently doing intubation. It was in the third group of cases that intubation showed its superiority. An intubation tube had the advantage of being worn for an indefinite time, thus producing constant and prolonged pressure; moreover, the size and shape of the tube can be easily changed so as to make it best conform to the needs of the individual case. Sometimes the intubation was secondary to tracheotomy, in which case it was better to do the tracheotomy as high up as possible. The longer a tracheotomy tube remains in an adult trachea, the more difficult does it become to introduce the intubation tube. To prevent the coughing out of the intubation tube, Dr. John Rogers, of New York, had fitted a retention arm at right angle to the tube. This comes out through the tracheal wound. In order to determine the exact point at which this arm should be attached a hard rubber intubation tube is inserted, and is then touched with a hot wire through the tracheal wound. The small spot thus burned on the tube indicates the proper place for the retention arm.

Dr. E. Mayer showed a similar intubation tube with retention arm, together with a large, hollow introducing instrument that he had devised. This instrument was very valuable in adult cases of chronic stenosis, because it allowed of the introduction of the intubation tube without interfering with the patient's breathing.

Dr. W. E. Casselberry spoke of the many difficulties encountered in performing intubation in these cases, particularly if the patient's condition were so bad as to preclude laryngoscopic examination. Under such conditions, he would favor tracheotomy. He then described the well-known feeding position for intubated patients, which goes by his name, and insisted that it would succeed in every case, if properly employed.

Some Cases of Paralysis of the Right Vocal Cord.—Dr. J. W. Farlow, of Boston, reported four of these cases.

Drs. Delavan, Casselberry, Swain, and Price Brown also reported their experience in this field.

A Report of a Method of Local Treatment Employed to Eradicate the Susceptibility of the Nasal Mucous Membrane to Hay Fever.—Dr. Clarence C. Rice, of New York, read a paper with this title. He expressed his belief in the theory that an abnormal sensitiveness of the nasal mucous membrane is a very important element in the production of summer coryza. He had accordingly tried to reduce this sensitiveness, in cases of false summer coryza, by frequently repeated frictional rubbings, carried on for several weeks before the expected attack. At first this rubbing with the cotton applicator was painful, and caused much coryza and discomfort. Each spot was rubbed ten or twelve times, with the applicator moistened with a solution of alumnol, fifteen or twenty grains to the ounce of a vehicle fifty per cent. of which is some one of the popular disinfectant solutions, and containing one-half per cent. of eucaine.

Dr. F. H. Bosworth said that the essential pathology of hay fever, in his opinion, was a vasomotor paresis arising from some irritation, such as pollen in the atmosphere, and occurring in persons of a neurotic temperament. The latter must be reckoned with in addition to diminishing the sensitiveness of the nasal mucous membrane.

Dr. Shurley, of Detroit, said that one should constantly

keep in mind the fact that this disorder is neurotic and the vaso-motor paresis only accidental. The rational cure of these cases depends upon the successful general treatment of the individual.

Dr. J. O. Roe, of Rochester, said that, unlike the author, he had never met with a case of hay fever occurring in a person having anatomically normal nostrils. According to his own experience, the middle and superior turbinates had more to do with the local irritation than had the inferior turbinate.

The Cleft Palate and its Relation to Speech. Dr. G. Hudson Makuen, of Philadelphia, was the author of this paper. He said that both the tongue and the palate were important in the function of speech, but the palate was the more important. The purely vocal elements of speech, such as the vowel signs, may be articulated when the palate is defective, but their resonance is so impaired that they are scarcely recognizable. Of the twenty-three consonant sounds only two, "m" and "n," can be articulated intelligibly when the palate is not intact, because in the pronunciation of the other consonants the palate is necessary to prevent the passage of the column of air upward. Perforation of the palate affects speech to a greater or less degree, dependent upon its position. Surgical measures for the relief of cleft palate should be undertaken as early as possible in the formative speech period, and these should be supplemented by instruction and practice in the normal production of speech. However skilful the surgeon may be in uniting the lateral halves of the palate, there would be inevitably a certain tension of the palate, hence, even though the operation may appear to be thoroughly successful, the result would not be a perfect substitute for a normal palate. There always remains some space between the velum palati and the posterior pharyngeal wall, and the muscles of the velum, because of the tension of this part, are almost wholly inactive. He had advocated, some years ago, minor surgical measures for increasing the size of the velum in these cases. They consisted in separating adhesions, forcible and repeated stretching of the velum with the finger after division of certain fibres of the palato-glossal and palato-pharyngeal muscles, training and development of the velum palati muscles by both direct and indirect voluntary procedures. The result had been marked improvement in speech in cases following the operation for cleft palate.

Note on the Use of the Electromagnet for the Extraction of Foreign Bodies from the Air Passages.—Dr. A. W. de Roaldes, of New Orleans, described some experiments that he had made with the Hobbs giant electromagnet on the cadaver, with the object of demonstrating the practicability of the method in removing metallic foreign bodies from the air passages. A roofing nail, weighing seventeen grains, and one inch in length, a steel button weighing fifteen grains, and five-eighths of an inch in diameter, were among the foreign bodies experimented with. The zone of attraction of these bodies was experimentally determined, with the result that the nail was attracted at a distance of nine inches, and the button at a distance of eight inches, when placed in a glass tube lined with leather. These bodies were then introduced into the trachea and bronchi through a tracheotomy wound, and were easily extracted by the magnet held at the level of the wound. In one experiment, the button was moved along from the bronchus upward, and again from the subglottic space downward to the tracheal wound, by the application of the magnet to the skin. For future use, he had had made several vertebrated metallic probes or bougies, which are to be attached to the giant magnet, and thus serve practically as extensions of its core. By an improvement in the construction of the magnet, a traction force of between two and three pounds can be utilized. A commutator is provided so that the current can be applied intermittently, and the foreign body to be extracted thus coaxed along by a series of magnetic pulsations, rather than by steady traction.

The Surgery of Nasopharyngeal Tumors.—Dr. D. Bryson Delavan, of New York, read this paper, and in it called attention to the work that had been done in this field by a recently deceased fellow member, Dr. R. P. Lincoln. The author expressed regret that the method advocated by that observer had been largely forgotten. He said that he had been able to find comparatively few reports on this method in the last ten years—the method devised by Voltolini. He had collected forty-five cases of preliminary operation done in this period, and of these in twenty-five, or fifty-three per cent., the results had not been stated. In five cases, or eleven per cent., failure had been reported, and in thirty-three per cent. there had been cures. Of seventy-two cases treated by the method advocated by Lincoln, twenty-six had resulted in a cure, two had failed, and in forty-four the result had not been stated. Unsatisfactory indeed were such statistics. Dr. Delavan said that he had had the same disappointing experience in collecting statistics on laryngeal cancer. In the method under discussion, the cautery snare, and not the snare was recommended, because it was the heat that divided the tissues and prevented the hemorrhage.

Pedunculated Fibroma of the Œsophagus Obstructing the Larynx.—Dr. F. C. Cobb, of Boston, reported this interesting case.

Officers Elected.—*President*, Dr. J. W. Farlow, of Boston; *First Vice-President*, Dr. J. W. Gleitsmann, of New York; *Second Vice-President*, Dr. D. Braden Kyle, of Philadelphia; *Secretary and Treasurer*, Dr. J. E. Newcomb, of New York; *Librarian*, Dr. J. H. Bryan, of Washington, D. C. The next annual meeting will be held at Boston, Mass.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 6, 1901:

	Cases.	Deaths.
Measles	275	18
Diphtheria	153	34
Laryngeal Diphtheria (Croup)		
Scarlet fever	220	33
Smallpox	91	25
Chickenpox	44	
Tuberculosis	166	150
Typhoid fever	24	14
Cerebro-spinal meningitis		5

Malaria and Typhoid Fever.—The record of cases in which malaria and typhoid fever have coexisted is not yet an extensive one, or rather the cases in which a thoroughly reliable diagnosis has been made are not numerous. At a recent meeting of the Lancisian Society of Rome, Fiocca, who is known for his accurate investigations in connection with Widal's reaction, reported an indubitable instance of this combination. The patient, who had never previously been ill, paid a visit on October 4th to Leprignano. On the 15th, he was attacked with malarial fever, and was admitted to the hospital of St. Giacomo, where he remained until apparently cured, the 30th of the same month. He then returned to Leprignano, but was again taken ill, and had to be re-admitted to the hospital on November 25th, suffering from a fever which continued till December 28th, with symptoms of typhoid fever, the blood giving a positive Widal reaction, but showing no malarial parasites. After the latter date, followed six days of complete apyrexia, and then on January 4th, another attack of malaria, with the presence of estivo-autumnal parasites in the blood, which

soon yielded to quinine. On the 10th, the temperature again rose, ushering in a relapse of typhoid fever, which continued until January 22d, when another period of apyrexia followed, lasting nine days. On January 31st came another relapse, this time of malaria. Again quinine was employed with good effect, since which time the patient has kept quite well. Here, then, were present simultaneously the infections of both malaria and typhoid fever, the former detected by the parasites found in the blood, the latter by the agglutination reaction of Widal which was obtained at different periods, and varied in intensity from a dilution of 1 in 50 to one as high as 1 in 500. It would appear that in this case there was a tendency for the two diseases to keep themselves distinct and independent; when one ceased, the other, after a short interval, began. This alternation could have been due only in part, if at all, to the action of the quinine, which was not administered in large doses until after January 15th.—*The Lancet.*

Sir Walter Besant.—The following generous appreciation of the late Sir Walter Besant appeared in *The Lancet* June 15th: "The late Sir Walter Besant was a philanthropist in the most literal sense of the word. He loved his fellow-men, and spared no pains in their behalf. Of the most genial temperament, and delighting in the happiness of others, the gray, depressing lives of the poor of London moved him to deep pity. A tireless worker, his heart bled for the seamstress whose day of labor was longer even than his own. A successful man, from the opening of his literary career, his sympathy went out to all of his craft, whose labors met with no return. His vision of a People's Palace to bring light into gloomy Whitechapel became a reality; his scheme for organizing men and women of letters into a coherent body for the maintenance of their common rights resulted in that useful corporation, the Society of Authors. Of Sir Walter Besant, as a scholar, a humorist, a novelist, and an antiquary, much might be written and will be written. But from a medical point of view, it will suffice to say that the healthy recreation which his sane and beautiful stories brought to a vast circle of readers had its physical value, while his vivid and picturesque portrayal of eighteenth century manners served to make us understand the processes of social evolution in a way that no dry-as-dust treatises could aspire to do. The death of such a man, devoted to well-doing, whose sanguine energy insured a practical effect for the dreams of his well-dowered brain, is a loss to the world, and we desire to pay tribute to our sense of this loss."

The Inconsistency and the Bigotry of the Antivivisectionist are illustrated by the occupancy of the president's chair at the recent annual meeting of the National Antivivisection Society, in London, by a personage who expressed a sense of shame for the horrors that went on in English laboratories, but who exhibits no qualms for the destruction of, and the suffering inflicted upon, birds for the mere pleasure and delectation of himself and his friends.

Tetanus Treated with Antitoxin.—J. W. Humrichouse in relating the history of a case, concludes as follows: 1. While it can be proved that the case here related recovered through the use of antitoxin, it is probable, for the reason that improvement followed its use. 2. The difference in mortality is slight between cases treated with and cases treated without antitoxin. 3. The non-efficiency of the serum treatment is due to its administration after the onset of the disease, when the poison has been absorbed by the nerve-cells of the cord. 4. The efficiency of the serum lies in its neutralization of the toxins in the blood, and the prevention thereby of their effect upon the nerve-cells. 5. Antitoxin should be used immed[illegible] wound, such [illegible] or a toy-pistol w[illegible] as soon as slight [illegible] 6. Antitoxin will [illegible] in animals and man [illegible] hospitals and places where tetanus is [illegible] demic.—*Marquis Medical Times.*

Gout in Connection with Lead Impregnation. [illegible] poisoning is a predisposing factor [illegible] dence which is adduced in support [illegible] Among hospital patients who suffer from [illegible] proportion are found to be affected with [illegible] viously suffered from lead poisoning. [illegible] are subject to gout are usually susceptible [illegible] ism, while it is also found that gout may be [illegible] the administration of lead salts in those who are predisposed to it, and the relation of cause and effect is shown from the fact that the latter ceases on the discontinuance of the former, and recurs on its repetition. Under the influence of lead salts the blood becomes abnormally charged with uric acid, while there is a corresponding deficiency of it in the urine.—DR. LORIMER, *in the Glasgow Medical Journal.*

Intestinal Ulceration in Arteriosclerosis.—This condition is described by Mouisset in two cases. It was found to be most marked in the colon. There were superficial ulcers varying in size from a pea's head to that of a franc piece; in one case there were as many as a hundred ulcers. The ulceration is regarded as due to fibrosis of the wall of the bowel—arteriosclerosis of the intestine—combined with narrowing of the blood vessels. The first stage in the process was a hard, raised patch in the mucosa. Subsequently ulceration supervened. In young persons dying with uræmia from scarlatinal nephritis, ulceration is very rare, inasmuch as arterial changes have not had time to develop. The ulceration of the intestines was, it may be pointed out, described years ago by Dickinson in his Croonian lectures (*Brit. & Medical Journal*, 1870, vol. i., under the title, "Albuminuric Ulceration of the Bowels." He regarded the primary lesion on which the ulceration was consequent as a hæmorrhage into the submucous coat of the bowel.—*The Practitioner.*

The Pulse in Peritonitis.—Again and again it has been pointed out that the pulse is the great guide when the peritoneum is involved, and that notwithstanding the favorable character of other symptoms, if the pulse remains quick, we have no right to be satisfied with the condition. The converse, however, may not hold true. A case recorded in *The Lancet* by Bowlby and Steedman serves well to show how careful we must be not to place reliance upon single symptoms; for here, although the abdominal cavity contained about a quart of dark, blood-stained fluid, and the greater part of the small intestine was so twisted as to form a large volvulus, the pulse remained below 100 in spite of the strangulation of so large a mass of intestine, and although the patient was evidently much collapsed and in intense pain. The case was a very remarkable one in other respects, this volvulus having come on after a previous operation for perforated gastric ulcer, in which rigors had occurred, but the authors draw special attention to this question of pulse rate, saying: "It is seldom that so serious a condition as was found in this case on opening the abdomen causes so little disturbance of the pulse rate; but this case, and others which we have seen, should serve as a warning not to place too much reliance on a quiet pulse when the question of laparotomy is under consideration for the relief of such suspected conditions as perforated gastric ulcer and volvulus."—*The Hospital.*

Measles and Vaccination.—The favorable influence of vaccination on whooping cough has been frequently noticed, and, as has been already suggested in this journal, is probably an example of the principle expressed in the ancient Hippocratic aphorism that "spasmodic diseases are cured by fevers," which is sometimes strikingly exemplified in the case of chorea. According to Dr. Papadelios, of Athens, however, vaccination exerts a similarly favorable influence in cases of measles, and he quotes several instances in which children attacked by the disease, during the reaction to vaccination, had it in a much milder form than other members of the same family. If this be confirmed it will add another to the numerous instances of bacillary antagonisms.—*Medical Magazine.*

The Ventricle of the Larynx as a Harbor for Diphtheria Bacilli.—Jobson Horne relates two case of diphtheria, occurring in young children, characterized by croupy cough and threatening dyspnœa, requiring tracheotomy. Faucial evidences of diphtheria and glandular enlargement were both lacking. Mouth cultures at two different times were negative. After the trachea was opened, some membranous-looking material was coughed up and examined but showed only staphylococci. Antitoxin was used but the first patient died. At autopsy there was found no membrane in pharynx or larynx. The tracheal wound was healthy except that the edges were surrounded by a whitish adherent membrane. Serum-agar cultures made from the freshly exposed surfaces of the larynx and trachea showed no bacilli but cultures made on the same media from the interior of the laryngeal ventricles yielded a positive result. Horne believes that the facts explain those fatal cases of so-called membranous laryngitis which, owing to the bacilli not having been found, have been regarded as non-diphtheritic, but which are really cases of true diphtheria; the facts may also explain some of those recurrences of diphtheria in which external sources of infection can almost certainly be excluded in the second attack.—*Journal of Laryngology.*

Water as a Vehicle of the Typhoid Germ.—The *Sanitary Record* says that the reference in Sir Henry Colville's book to the causes of typhoid fever in Africa has given rise to considerable comment in the daily press, and has called forth one or two interesting letters from private individuals. One of these, giving the personal experience of the writer in the Australian gold fields is worthy of note, not because of any striking originality, but because of the experience it records. Writing to the *Morning Post*, "Prospector" says: "I would point out that the experience of medical men on the West Australian gold fields—where typhoid fever was in earlier days a terrible scourge—points to bad water as the chief source of infection. Fevers have practically disappeared from Kalgoorlie and Coolgardie, now that pure condensed water is obtainable, and Cue is quite a healthy town, though six years ago the normal death rate was one per cent per annum among the pioneers—to all intents and purposes picked men physically, in the prime of life. In those days drinkable water came from surface pools, and was very dangerous stuff to tackle, but subsequently numerous wells were sunk, and good water is abundant. I have heard the dust theory advanced, but do not think there is much in it."

Freezing Point of Blood.—Koranyi, of Budapest, claims that the freezing point of blood is a diagnostic sign of renal activity. The normal point lies within the narrow limits of .56 and .58. When .50 is reached, there is a decided functional loss of the kidney, and when both are affected, respiration is seriously interfered with. He admits the cause may be either reflex or mechanical or both.—*The Medical Press.*

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, United States Marine Hospital Service, during the week ended July 6, 1901:

		CASES	DEATH
SMALLPOX—UNITED STATES AND INSULAR.			
California, Los Angeles	June 1st to 22d	7	
Illinois, Chicago	June 22d to 29th		
Indiana, South Bend	June 22d to 29th	1	
Iowa, Clinton	June 15th to 22d	1	
Kansas, Lawrence	June 15th to 22d	1	
Wichita	June 15th to 30th	3	
Kentucky, Lexington	June 22d to 29th	1	
Louisiana, New Orleans	June 22d to 29th	2	
Shreveport	June 22d to 29th	3	
Massachusetts, Fall River	June 22d to 29th	3	
Waltham	June 22d to 29th	1	
Worcester	June 14th to 21st	1	
Minnesota, Minneapolis	June 15th to 29th	15	2
Winona	June 15th to 29th	3	
Nebraska, Omaha	June 22d to 29th	7	
South Omaha	June 24 to July 1	3	
New Jersey, Bayonne	June 23d to 30th	1	
New York, New York	June 22d to 29th	97	15
Ohio, Cincinnati	June 22d to 28th	1	
Cleveland	June 23d to 29th	8	1
Pennsylvania, Philadelphia	June 22d to 29th	3	
Pittsburg	June 22d to 29th	1

THE SUTURE OF WOUNDS OF LARGE BLOOD VESSELS, WITH REPORT OF A CASE OF RECOVERY AFTER SUTURE OF A WOUND OF THE AXILLARY ARTERY.

BY A. E. HALSTEAD, M. D.,

CHICAGO,

PROFESSOR OF SURGERY, CHICAGO POLICLINIC; ATTENDING SURGEON TO THE COOK COUNTY HOSPITAL.

MRS. S., aged 43, was operated on by me in the latter part of May, 1900, for advanced mammary carcinoma. At this operation the whole mammary gland, with both pectoral muscles and their fascia and the axillary glands and fat, were removed in one mass by sharp dissection. The infraclavicular glands were slightly enlarged and were also removed. No change in the cervical glands was noted at this time. Four months later the glands along the posterior border of the sternocleidomastoid began to enlarge, and were removed. They were found to be carcinomatous. About the middle of October a small nodule began to grow at the outer end of the clavicle, which was somewhat deeply seated and painful. In two weeks the pain disappeared, and the nodule appeared to diminish in size. In the latter part of November the tumor again became painful, and rapidly increased in size. On December 14 the patient presented herself for examination, when a tumor about the size of a walnut could be felt, deeply seated, just below the coracoid process. She was advised to have this tumor removed, and accordingly was sent to the Polyclinic Hospital, where, on December 14, under ether anæsthesia, an incision was made parallel with the old line of incision, curving downward and outward from the middle of the clavicle to the floor of the axilla. The tumor was found to have originated in the short stump of the small pectoral muscle, which was left attached to the coracoid process. It had pushed up the inner fibres of the deltoid to which it had become adherent, and had involved the upper part of the coracobrachialis and the capsule of the shoulder joint. The coracobrachialis and the inner third of the deltoid were dissected from below upwards, and with the tumor, the part of capsule involved, and about two inches of the axillary vein, were removed.

Just before the dissection was completed, the axillary artery was found adherent by its fascia to the tumor at a point about on a level with the insertion of the pectoralis minor muscle. By means of sharp, curved scissors the artery was being freed from its attachment to the tumor, when the vessel was accidentally cut obliquely through about two-thirds of its circumference. Violent hemorrhage, of course, immediately followed, which was controlled by placing the index finger of the left hand under the artery and pressing it up against the clavicle. The operation field was then sponged dry and the wound of the vessel inspected. At the time of the first operation all the branches of the axillary artery excepting the circumflex had been cut, so that there was practically no chance for collateral circulation being established. Under the circumstances, the only chance of saving the arm was to suture the artery. Accordingly, while the circulation was controlled by pressure of the left index finger, four interrupted catgut sutures were passed through the two outer coats of the vessel and tied. This effectually closed the wound in the vessel, so that no hemorrhage followed removal of pressure from the artery. To support these sutures the perivascular connective tissue was sutured longitudinally with a fine catgut suture. The tumor was then dissected from the vessel, and the wound closed in the ordinary way. The radial pulse was immediately restored, and was as full as that of the opposite side. The patient made a good recovery from the immediate effects of the operation, and had at no time any disturbance of the circulation of the arm. She left the hospital at the end of two weeks. Two months after the operation there was still a radial pulse on the left side of a volume equal to that on the right.

It is only during the last twenty years that the conservative treatment of wounds of large blood vessels has received any attention, although Lambert, a surgeon of Newcastle, successfully sutured a wound of the carotid artery in 1762. No other attempt is recorded until Czerny, in 1881, sutured a wound of the internal jugular vein. The publication of two unsuccessful experiments on animals by Assmann in 1773, and the condemnation of the operation by Broca and other surgeons of his time, resulted in preventing further advances in this direction until the experimental work of Schede, Glück, and Von Horoch demonstrated not only that longitudinal wounds of large vessels could be successfully sutured, but that circular union of divided arteries was possible. The publication in 1891 of the results of the experiments made by Jassinowsky did more to revive the interest in suture of blood vessels than did any previous work on this subject. His experiments, twenty-six in number, were made on the carotids and abdominal aorta of dogs. The length of time the animal was permitted to live after the vessel was sutured varied from one hour to 105 days. The wounds sutured were of all kinds—longitudinal, oblique, and transverse.

The results of these experiments demonstrated that suture of a wound of a blood vessel with subsequent healing could be accomplished without a serious risk of aneurism or hemorrhage, providing aseptic wound conditions were maintained. It was also demonstrated that closure of the wound was accomplished principally by the proliferation of the endothelium of the intima and of connective tissue cells of the adventitia.

Following Jassinowsky's work, we have the publication of the experimental studies of Muscatello, Tichow, Orlow, Nitze, Bruci, Doerfler and others, whose results were on the whole similar to his. In 1894 Abbe experimented with end-to-end union of blood vessels, employing glass tubes, placed inside the

lumen of the vessel to support the approximated ends. In 1895 Israel sutured a wound of the common iliac, which was accidentally made during an operation for appendicitis. The same year Zoege von Manteuffel sutured successfully a wound of the femoral, and Heidenhain an oblique wound of the axillary artery, made while operating on a carcinoma of the breast. Murphy, in 1897, published a paper in which he detailed his results in a large number of experiments on animals, demonstrating the practicability of end-to-end union of arteries by suture. He also reported two cases; in one the femoral vein was sutured and in the other a portion of the femoral artery was resected and the ends were united by invagination and suture; both patients recovered. Among the others who have reported successful cases of arterial suture may be mentioned Lindner, who sutured the femoral, Zeigler the carotid, Kümmell the femoral, Garrie the brachial and common carotid and the popliteal. Of the large veins, the jugular, subclavian, and the femoral have been sutured a number of times. Manteuffel successfully closed a wound of the inferior vena cava, which had been made in the removal of a carcinoma of the kidney.

The indications for arterial suture are: First, in all cases of injury to a vessel or vessels, where a ligature might bring about serious nutritional changes to the part supplied by the injured vessels. This is especially apt to occur when the corresponding vein is injured at the same time. In such cases an effort should be made to repair both vessels, although if the arterial circulation is established the necessity of restoring the continuity of the vein is not so imperative. Second, in all wounds of large vessels produced by puncture, gun-shot, or laceration. Third, operation wounds of large vessels, accidental or intentional, as when, for any reason, a part of the vessel must be sacrificed.

In wounds involving no more than one-half of the circumference of the vessel, either oblique or transverse, simple suture only is required. When more than one-half of the circumference is involved, resection and end-to-end union by invagination will constitute the best method of treatment. In the case just reported an oblique wound of two-thirds of the circumference of the vessel was sutured without difficulty and without subsequent obliteration of the artery. It has been demonstrated by experiments on animals that after invagination, or when end-to-end union is accomplished by any method, the vessel in most cases ultimately becomes obliterated, as a result of endothelial proliferation. This, however, does not occur immediately, but usually after several weeks have elapsed. The fact that the artery may thus be obliterated cannot be used as an argument against the conservative treatment of wounds of these vessels. If the direct circulation through the artery is permitted to continue for even a few days as the result of the suture of a wound, and is not suddenly cut off, as it is when the vessel is ligated, a sufficient collateral circulation will have been established to prevent any serious nutritional disturbances of the tissues supplied.

In considering the indications for arterial suture it is evident that only in wounds of a few of the larger arteries is the operation indicated. In the medium sized and small vessels there is no danger of necrosis of the vessel is ligated. Again, suture of a small vessel would be impossible. Of the large vessels where suture is important we may mention the aorta, popliteal, common carotid, subclavian, axillary, femoral, and iliac. In subcutaneous rupture of the popliteal, or in gun-shot wounds, the vein is nearly always injured because of its relation to the artery, and in nearly all cases a necrosis of the leg and foot follows. Wounds of the aorta may be successfully sutured. If we consider the results of ligation of the common carotid, the value of suture of wounds of this vessel is readily apparent. According to Pilz, the mortality following ligation of the common carotid after injury is 54 per cent.; Klemm puts it at 41 per cent. Zimmerman collected all the cases published between the years 1885 and 1891 in which the common carotid had been ligated for any cause, and found the mortality to be 41 per cent. Pilz also found, in his review of published cases, that in 32 per cent. of all cases brain symptoms followed; of these 56 per cent. ended fatally, the cause of death being ischæmic necrosis or hemorrhagic softening. Of the cases of wounds of the carotid conservatively treated by suture, so far all have recovered without any untoward symptoms.

In dealing with the technique of suture of wounds of blood vessels we have to consider the means of securing temporary hemostasis, the suture material to employ, and the manner in which the sutures are to be introduced. It is scarcely necessary to state that there should be a perfect aseptic condition of the wound. The operation should never be performed in the presence of septic wound conditions. Of the methods of temporarily controlling the flow of blood through the vessels we have (1) elastic constriction, (2) digital compression, (3) temporary ligation, and (4) pressure by properly protected hemostatic forceps. In cases in which it is possible, as in wounds of the popliteal or femoral, the circulation can best be controlled by elastic constriction. In other parts of the body where this means cannot be employed, digital compression, preferably by pressing the vessel against a strip of gauze placed underneath it, as practiced by Murphy, is the most convenient and safest procedure. The use of hemostatic forceps having light, flexible blades, which have been covered by pieces of rubber drainage tube, has been found satisfactory where other methods were not available. There is, however, always great risk of permanently injuring the vessel when the forceps is used. Temporary ligation with an ordinary silk or catgut ligature is dangerous, and should not be employed.

Since operating on the case just reported, in doing experimental suture of arteries on dogs, I have secured temporary control of the circulation by passing a loop of tape around the vessel and twisting it until the lumen of the vessel is closed, and then holding the tape by means of an artery forceps, applied close to the vessel. With this method the wall of the vessel is not injured, and the ligature can be quickly removed after the suture is completed. This method also has an advantage over digital compression in that it excludes from the field of operation the hands of an assistant that are in the way and that may be a source of infection.

In the selection of suture material, some operators prefer catgut, others silk. The chief advantage claimed for the catgut is that when it becomes moistened, it swells and closes the needle punctures, thus controlling the hemorrhage which frequently occurs. Many prefer silk for suture because it supports the line of union longer than the catgut, and also because, being non-absorbable, it acts as a foreign body and stimulates the proliferation of the connective tissue and endothelial cells and thus adds strength to the cicatrix. The experiments of Tichow go to show that when silk is employed it never shows any tendency to pass into the lumen of the vessel but always in the opposite direction. Doerfler found in his experiments, that when the animals were killed in from one to four days the suture remained unchanged. After five to eight weeks, the sutures were no longer

visible in the lumen of the vessel, their position being marked only by a circumscribed thickening of the intima.

In introducing the suture, some include only the adventitia and media, while others penetrate all the coats of the vessel. Jassinowsky strongly advocates the former. He claims that in not penetrating the intima, the risk of thrombus and of hemorrhage from the needle punctures is lessened, and that secondary hemorrhage is not so apt to occur. On the other hand, Doerfler is equally positive that there is no good reason for not including the intima, and that technically the operation, when all the coats are penetrated, is not so difficult as when only the outer two are included. In the suture of longitudinal wounds of arteries, it is best to use a continuous catgut suture penetrating only the two outer coats of the vessel. After the wound has been closed an additional suture of the perivascular connective tissue over the wound in the vessel will add strength to the line of union. If the intima is penetrated the slight hemorrhage from the needle puncture, which always follows, can be controlled by pressure exerted for a few moments. The needle should always be a fine, round, curved intestinal needle. In complete and transverse wounds of arteries, or when more than one-half of the circumference has been divided, the best method of uniting the divided ends is the invagination method of Murphy, the proximal end being invaginated into the distal by means of two or three silk sutures which are first fastened to the proximal end and then passed through the walls of the distal end from within outwards. Tying these sutures draws the proximal end into the distal. After this, four or five interrupted sutures penetrating only as far as the intima of the invaginated vessel are used to bind the two together.

Other methods of securing end-to-end union of arteries have been attempted. Glück and Nitze devised ivory and rubber rings to secure the ends of the divided vessel. Recently Payr, after a long series of experiments and clinical study, suggested the use of a metal tube which is slipped over the distal end, leaving about one-half an inch of the vessel projecting through the ring. This is then turned cuff-like back over the ring, so that the intima is external. The proximal end is then turned over this cuff and fastened by a ligature which fits into a groove in the ring. He also experimented with a metallic coupler similar to the Murphy intestinal button, which he used for securing end-to-end union of arteries. These rings and couplers were made of metallic magnesium which was found to be rapidly absorbed when imbedded in living tissue. Experimentally, Payr's device was fairly satisfactory, but so far it has not been used on man.

In the treatment of wounds of arteries where there has been a loss of substance, it has been suggested by the same author that the opening be closed by a magnesium plate fastened between the adventitia and media. In a wound of the common carotid of this kind, when resection with end-to-end union could not be accomplished, Glück closed the defect in the artery by suturing over it a flap taken from the internal jugular vein.

After the suture of any large blood vessel the operation wound should be closed by buried sutures of catgut without drainage. The accurate coaptation of the edges of the wound will materially support the injured vessel and act as a safeguard against hemorrhage.

CLINICAL OBSERVATIONS ON SYPHILIS.*

BY J. A. FORDYCE, M. D.,

NEW YORK,

PROFESSOR OF DERMATOLOGY AND SYPHILOLOGY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Gangrene of the Initial Lesion.—I recently observed the occurrence of gangrene in an initial lesion which rapidly spread and in two days had involved half the glans penis. The patient presented no phimosis or paraphimosis; he was in good health and was not addicted to alcohol.

The induration which was previously present beneath and about the slight ulcer disappeared in the destructive process. The absence of secondary sores from auto-inoculation, the antecedent induration with characteristic inguinal adenopathies rendered a diagnosis of an initial sclerosis probable. This view was subsequently confirmed by the reappearance of induration after the cessation of the gangrenous process and later by the appearance on the trunk of scattered lenticular papules. The rash was carefully observed with a view to detecting any rapidly destructive change in the infiltration allied to that of the initial lesion, but its evolution has been fairly typical. Aside from conditions of the tissues which are due to a general cause such as diabetes, alcoholism, etc., we know little of the etiology of the condition in question. Secondary infection with other organisms than those of syphilis may be responsible for it, or we may reasonably infer that an increased virulency of the syphilitic poison itself may be sufficient to kill the tissues *en masse*. The luetic infiltration, at best, is characterized by a short life, necrosis of the granuloma sometimes taking place as soon as it appears or even before a definite type of lesion can become established. This tendency to rapid cell destruction, which is a marked feature of the disease, together with the changes in the blood vessels which lead to partial or complete obliteration of their calibre, may be contributing factors or wholly responsible for the spreading gangrene.

In treating this rather unusual complication of the initial lesion I have found that chlorinated soda solution, either in full strength or diluted according to the tolerance of the individual, has an exceedingly rapid and beneficial effect, its germicidal power being due in great measure to the free chlorine which penetrates the tissues more promptly

* Read before the fifteenth annual meeting of the American Association of Genito-Urinary Surgeons, May 1, 1901.

than the more commonly employed antiseptics. The cure was facilitated by the free use of iodoform, which finds its field of greatest usefulness in all local sloughing sores.

Secondary Syphilis.—While the differential diagnosis of the primary sore does not involve the consideration of many other conditions, the situation is quite otherwise when we consider the possibilities in the secondary stage of the disease.

The acute exanthemata, eruption from the administration of drugs, and a multitude of non-venereal eruptions may confuse the physician if all the concomitant symptoms are not given their proper consideration. It is not an unusual occurrence during epidemics of small-pox for the generalized pustular eruptions of syphilis to be confounded with the former disease. I recall distinctly, a few years ago, the admission to one of our large city hospitals of a patient having a generalized papulo-pustular eruption with the erroneous diagnosis of syphilis. The mistake was not discovered until the death of the patient and the outbreak of variola among a number of the exposed patients and hospital attendants.

Such generalized eruptions in syphilitic patients are sometimes preceded by a considerable rise of temperature.

The initial sore, too, may escape observation by reason of an out-of-the-way location, or an insignificant development causing such errors in diagnosis to be readily made.

The eruption in measles is less apt to be confused with the macular syphilide, but such mistakes may and do occur. I saw at one time a young girl at my clinic with a pronounced macular eruption, a conjunctivitis and a catarrhal inflammation of the pharynx, a combination of symptoms which strongly suggested measles. A closer examination of the patient revealed a primary lesion on the genitals and other indications of syphilis.

After the disappearance of the chancre and nodular swelling, the character of the eruption alone is all that we have to guide us in making a diagnosis if the past history is obscure, or if the patient is of the usual dispensary class, lacking in power of observation and careless of the minor ailments of life.

Impetiginous eruptions from pus organisms may at times closely resemble the larger pustular lesions in syphilis, which occur later in the secondary stage. The latter are, however, apt to affect the deep layers of the skin and to heal with the producing of pigmented scars.

A disseminated sweat-gland inflammation, beginning as deep-seated papules and leading to local necrosis of the surrounding tissues, followed by a depressed pigmented scar, is almost identical in appearance with certain syphilitic eruptions. One is often unable to make a correct diagnosis until after mercury has been given a thorough trial.

Lichen Planus and Syphilis.—Diagnostic skill in recognizing unusual types of syphilis of the skin can only be obtained through prolonged clinical experience.

The observer of the widest experience, is, however, sometimes confronted with eruptions of a non-venereal nature, which simulate in the closest manner those of syphilis. It must be borne in mind that the vascular apparatus of the skin may react in a similar manner to irritants of a widely divergent nature, so that from the appearance of the rash alone errors in diagnosis may easily be made. Certain generalized forms of lichen planus, as in the case reported by me[1] may readily be mistaken for the papular or papulo-squamous syphilide. In this case there were grouped papules with circinate or gyrate outlines having pigmented centers and surrounding areas of pigmentation. The development and involution of the grouped lesions simulating in a striking manner a relapsing syphilide.

Figure 1.—Pemphigus Vegetans.

When mucous membrane lesions accompany the skin changes in lichen planus, the resemblance of the affection to syphilis is even more striking.

The marked pruritis which is such a constant symptom of lichen planus, is usually absent from syphilis and should suggest the former affection.

Syphilis and Pemphigus.—A patient was recently admitted to one of my wards in the City Hospital with the following history:

Twelve years before he had contracted a venereal sore which was followed by a secondary rash. Two years later he had a peculiar eruption on the hands, arms and legs and soon after an ulcerated mouth. He described the eruptions as beginning with pea-sized red spots on which pustules developed; after a week or two they would heal, leaving dark areas of pigmentation. In the last ten years he has had five such attacks, each one lasting about two months and always accompanied by sores in the mouth. When seen by me he had numerous pea-sized pigmented spots on his body, especially noticeable in the palms, a few pustules over the forearm and several opaline spots on the sides of the tongue and mucous surface of the lips. He had been admitted to the hospital several times previously and always with the diagnosis of syphilis. One of the members of the house staff who had had some previous training in skin diseases

[1] *Jour. Cutan. and Genito-Urin. Dis.*, 1899.

recognized the resemblance of the eruption to pemphigus and called my attention to it.

The patient for ten years had been having a relapsing pemphigus, which had been mistaken for syphilis, partly because of the venereal history and partly on account of the objective features of the eruption.

A venereal history, relapsing eruption with pigment changes in the skin even when combined with mucous membrane lesions, are not necessarily pathognomonic signs of syphilis.

Neumann in 1886 first called attention to a variety of pemphigus with papillomatous lesion, which he called pemphigus vegetans. The disease presents such striking resemblances to syphilis that it is not surprising it has often been confounded with the latter disease. A patient with the affection was recently referred to my clinic and gave the following history:

He was twenty-nine years old, a plumber by occupation, and had always been well until two years previously. At that time blisters appeared in his mouth, axillary regions and about the pubes, finally involving a considerable portion of the cutaneous surface. He was then an inmate of the Skin and Cancer Hospital, and was seriously ill for some weeks with fever and other general symptoms. He remained well after the first attack for over a year, then lesions appeared in the same localities as in the former attack. He now has bullæ, pustules and dime-sized abrasions about the nose, chin and lips; on the inner side of the lips and tongue numerous erosions from ruptured bullæ are present, which interfere with mastication. Both axillary regions, the central part of the skin of the abdomen, the groins, inner sides of the thighs, the penis and scrotum were the seat of numerous bullæ pustules and papillomata with scattered pigmented spots marking the old lesions. (Fig. 1.) The evolution of the eruption can be traced from the clear bulla which first makes its appearance to the pustule and finally the warty outgrowth which springs up from the erosion left after the bulla or pustule ruptures.

His attack had lasted two weeks when he was first seen by me. He then had no fever, chills or other constitutional symptoms but the development of a serious condition could not be long delayed. The patient has since died.

At first glance the case bore a striking resemblance to syphilis, but on closer inspection the presence of bullæ springing from the apparently sound skin, the history of a previous attack and the absence of concomitant signs of syphilis rendered that diagnosis improbable. Bullæ as a manifestation of syphilis in the adult is rarely met with and then only in cachectic subjects.

Figure 2.—Superficial scaling syphilide ("en nappe") resembling psoriasis.

In pemphigus vegetans we have bullæ and papillomata with a rather definite distribution and clinical course.

It is a relapsing eruption which, as a rule, has a fatal termination.

Syphilis and Psoriasis.—A papulo-squamous syphilide is generally made up of rather small lesions which do not tend to run together in large scaling patches as in psoriasis of some weeks' duration. In the latter affection large areas of skin are often implicated by the enlargement of single lesions and the confluence of adjacent patches.

The eruption pictured in the illustration (Fig. 2), viewed on its merits, aside from the concomitant evidences of syphilis could readily be mistaken for psoriasis. The patient was admitted to my service with such a diagnosis and was treated with chrysarobin before the true nature of her eruption was recognized. The rash was very superficial, the scaling was profuse and at the margins circinate lesions were seen, which were evidently the primary manifestation of the eruption. The large patches on the upper extremity had evidently been formed by the confluence of the single spots, giving a clinical picture which was almost the exact counterpart of psoriasis.

A rather casual inspection of the patient's face and scalp revealed the true nature of the rash, for about her lips the syphilitic nature of the papules was at once apparent, as they involved the mucous as well as the cutaneous surface. The loss of hair, too, was typical and hypertrophic papules were found on the genital organs.

The patient stated that she had previously had a dry scaling eruption on the arms, which may have been a seborrhoic dermatitis and possibly modified the existing syphilide. Seborrhoic dermatitis as

has been shown by Unna and others, undoubtedly has some tendency to modify the type of a syphilitic eruption on the regions which are the site of predilection of the former disease.

An antecedent morbid condition of the skin may serve as a *locus minoris resistentiæ* and tend to localize the specific rash without in any way modifying its type. The patient, whose back is depicted in Fig. 3 came under my care with an initial sclerosis and a coincident seborrhoic dermatitis of the scalp, back and chest. A careful observation of the evolution of the secondary eruption showed that it appeared first on the regions which were the seat of the seborrhoic dermatitis. It subsequently became generalized, but was more copious on those parts without showing any definite departure from the type on the normal skin.

Syphilis and Lepra.—The following case will illustrate the failure of the therapeutic test as an aid in diagnosing obscure eruptions.

A South American was under my care during the past winter with a generalized eruption consisting of large patches of a brownish red color. Some of the patches were three inches in diameter and several of them had assumed annular outlines from the disappearance of the central color. A few of the patches were slightly thickened. He gave a definite history of syphilis and carried a scar from an old initial lesion which he stated was contracted in 1891.

Figure 3.—Seborrhoic Dermatitis and Secondary Syphilis.

In 1899 he had an eruption over his body which disappeared under mixed treatment. In the latter part of 1900 a generalized eruption again appeared similar to the one the previous year. He said that before his admission to the hospital the spots were elevated, hard, hypersensitive, but under the influence of mercury, administered subcutaneously, the infiltration rapidly subsided and the hyperæsthesia decreased. The patient as well as the physician were convinced of the syphilitic nature of the eruption because of its prompt response to mercury. A more careful examination of the patient showed a pronounced thickening and exquisite sensibility of both ulnar nerves and atrophy of the muscles of the ball of the left thumb. These conditions, together with an eruption which one would not expect to encounter in syphilis, pointed strongly to lepra, an opinion which was confirmed by the presence of lepra bacilli in a piece of tissue excised from one of the slightly infiltrated patches.

The eruption continued to fade while the patient remained in the hospital and after a few weeks had practically disappeared.

Crocker and others have noted the rapid subsidence of leprous nodules after intramuscular injections of the soluble salts of mercury. Lichen planus, which has been shown to localize on the skin in much the same manner as syphilis is at times favorably influenced by the internal use of mercury. The therapeutic test is, therefore, not an unfailing one in all cases where we look for help from it in diagnosis.

Exceptionally cases of syphilis are met with which refuse to heal or recur in spite of the most approved and carefully applied treatment.

Fournier[1] and other writers have noted instances of refractory syphilis in which all methods of treatment proved unavailing.

The writer has observed late hypertrophic nodular skin lesions about the face which did not yield to large doses of the iodides and mercurials until the new growths were freely curetted.

Syphilis and Lupus.—The late superficial serpiginous syphilides of the skin may at times closely simulate lupus vulgaris and while the differential diagnosis is usually not difficult, an exceptional case may come under observation which taxes our diagnostic powers to the utmost.

In the photograph Fig. 4 an extensive involvement of the skin by one of the doubtful cases is depicted in which vigorous treatment by large doses of iodide of potassium and mercurial plasters and ointments, was employed for a long time before the infiltration began to yield.

The scar tissue making up the center of the patch

[1] Traité de la Syphilis, 1896.

was not reinfected by lupous nodules, as we would expect to see in the tubercular trouble. The nose and cheek were involved at the same time with a granuloma which became fungating and was not favorably affected by anti-syphilitic treatment until the soft protruding tissue was freely curetted.

Tissue was excised for microscopic examination from both the thigh and face lesions.

Numerous giant cells were present in the sections which could not be distinguished from those met with in lupus.

The changes in the skin in the case in question differed, however, from those seen in lupous tissue. In syphilis the inflammatory foci are scattered here and there throughout the derma while in lupus the infiltration is continuous, looking more like a new growth than an inflammatory reaction. The connective tissue reticulum in lupus is more pronounced and is woven in and about the granulation tissue in a very characteristic manner.

In syphilis the exudation cells are grouped about certain vessels which early show obliterative changes.

66 Park Avenue.

Figure 4.—Superficial Serpiginous Syphilide resembling Lupus Vulgaris.

Dangers from Fresh Vegetables.—Dr. Ceresole has made a study of the importance of raw vegetables in the diffusion of parasitic diseases. He bought specimens of lettuce, endive, radish and celery in the market at Padua, such as would be used for eating after a rough washing. He then washed them in sterilized water and examined the sediment. A simple microscopical survey revealed a fauna of fifty-two species, comprising amœbæ and the eggs of tænia, oxyuris ascarides, and ankylostoma. Bacteriological investigations added a rich flora of varied microbes, including micrococci, staphylococci, streptococci, sacrinæ, and a wealth of bacilli. Among the last the author could isolate the bacilli coli communies and a bacillus analogous to that of typhoid, as well as the bacilli septicus and the bacillus tetani. The author advises all who are bold enough to eat raw market-bought vegetables after reading his article, to first wash and then soak them for half an hour in a three per cent. solution of tartaric acid, which is a cheap, agreeable and powerful antiseptic. A salad artificially impregnated with cholera spirilla was disinfected after five minutes' immersion in this solution.—*Medical Magazine.*

HEADACHES.*

By H. H. SEABROOK, M. D.,

New York,

Surgeon to the New York Eye and Ear Infirmary.

In former times when such medical knowledge as was extant could be fairly well mastered by the individual, searchers after general principles were apt to choose that organ of the body which seemed best likely to serve the purpose in hand, and the structure and functions of the eye were often found to be available in this way. The organ of vision was the first to become the object of special study and practice, and to be accepted more and more as having laws peculiar to itself. Occasionally it was yet forced upon the profession at large, as when Leber by his masterly work proved his contention that the eye offered a superlative field for comparison of the effects of chemical irritation and bacterial infection upon cell action.

The subject of headache is one of widespread interest, and the intimate connection between pain in the head and strain of the eyes is a matter of common knowledge. While ocular headache seems usually to be regarded as a condition to be differentiated from other forms, the writer has come to believe that this may be accomplished with certainty only by demonstrating the co-existence of ocular strain and headache and proving that the former is primary and the latter its consequence. An attempt will now be made to explain the headaches of eye-strain by what might be called direct mechanical theories, and to glance at certain elements in the production of other headaches.

The two forms of eye-strain generally recognized as causing headache are the accommodative or ciliary-muscle strain, from lack of proper glasses, and the muscular, from incoördinate action of the extrinsic ocular muscles in binocular fixation.

The simplest form of the first sort of strain is that which can be properly corrected with convex glasses, the headache is mostly frontal, occurs principally with near work, and is almost invariably relieved by the correction.

Another form of ciliary strain needs vertical rather than horizontal astigmatic glasses, the headache is frontal

*Read before the Society of the Alumni of Bellevue Hospital, March 6, 1901.

temporal, may extend further, or be accompanied by pain in the post-cervical region in susceptible individuals, and although more severe with near use of the eyes, may also occur with use for distant objects. Relief from the glass correction is marked or perfect, almost without exception.

When the eyes require astigmatic glasses with an oblique axis, headaches are more likely to be severe and general than in cases with the preceding errors, and accompanied by dizziness and nausea. The glasses cause temporary annoyance, but nearly always relieve the symptoms in a week or two in young patients who persist in using them, if the axes of the glasses for the two eyes are symmetrical. If the axes are parallel, relief is less likely to be obtained, and the results vary in accordance with optical effects in other combinations.

In the forms of astigmatism known as mixed and irregular there are special phenomena added to ciliary strain, caused by the intense effect of light upon the retina and sensory fibres within the optic nerve; glasses may relieve the strain, but do not properly remove the chemical irritation due to the light. In these cases glasses are usually partial or complete failures, so far as the relief of headache is concerned.

There are other points in connection with glass corrections too technical or too trivial to be introduced here. Improvements are going on, but it is safe to say that certain faulty focal conditions existing in eyes will never be met by art or science, and headaches caused by them never relieved.

Although ciliary strain is usually put ahead of the muscular in classifications, the action of the latter in producing headaches was known at as early an epoch as that of the former. Headaches are caused by a strain put upon muscles with tendencies to deviation, in order to obtain single vision. There is no reason to question this, the usual explanation for heterophorias, yet it should be supplemented by the observation that many persons with double vision from paralysis of ocular muscles have discomfort, dizziness, and nausea in consequence of the visual defects.

Among the most important abnormal tendencies of the muscles causing headache, are, first, a tendency to divergence; the pain may be frontal and severe, or, more often, general with dizziness and nausea. It is brought on or increased by near work, and disappears regularly after operation when the result as regards the muscular condition is a success.

Another of these muscle errors is a tendency to convergence. Headaches come on from prolonged use of the eyes for distant objects; they are severe, general, periodic, and accompanied with dizziness, nausea, and sometimes vomiting. When the muscular condition is secondary to errors requiring glasses, the latter, properly applied, relieve the headaches; prisms usually accomplish the same object in another class of cases. Operations may also be successful, but there are reasons why they not infrequently fail to produce a good result to the ocular muscles and the symptoms. These headaches may improve or disappear as age advances and convergence becomes weaker. A large number of tests show this; but, while divergence tendency and the consequent headaches increase with age, although after fifty years of age is reached arterial changes, chronic nephritis and the like impair the value of any deductions from the ocular standpoint.

The last muscular anomaly we shall consider at present is an upward tendency of one or the other eye. The headaches in these cases may take any of the forms previously mentioned, and systemic disturbances may be marked. There is a type of headache occurring in these cases, especially when oblique astigmatism is also present, which consists of general pain, with much greater severity on one side, as if from a superadded supra-orbital neuralgia—although there is no tenderness over the nerve. Treatment with prisms or tenotomies is very successful in relieving the symptoms when the ocular condition is properly corrected.

An infinite variety of actions of the ocular muscles exists in nature—using the word infinite in its mathematical sense. The three above mentioned are sufficient for our present purpose, and I find their consideration, with tests for distant and near vision, and others of the power of divergence, convergence, and sursumvergence, enough for my limited time and intelligence. The classification here presented for the purpose of studying headaches has been reduced to ultimate simplicity by leaving out errors of doubtful import, not considering the important but little understood phenomena peripheral to the line of vision, and translating, when possible, into English; yet the first two glasses mentioned must be combined in one form compound astigmatism, and although concave glasses were not considered, myopic astigmatism, simple and compound, surely causes strain. We have thus kept our single errors down to ten, the refractive and muscle errors combined number thirty-three, and there are two double muscular errors. The latter combine with the eleven errors of refraction mentioned*, making twenty-two triple errors, or sixty-seven in all, to correct, for which we apparently have ample means. If we stick to the test case in .25 Ds, which the .12 D men consider out of date, it is because we think we are able to correct fairly well most of our cases; for if we combine the sixty spherical and thirty-six astigmatic glasses therein contained we can get two thousand one hundred and sixty combinations, and most of us are content with 180° in the arc for the axis of any one of them, even for strong glasses, although we like to see a man get down to parts of a degree in his orders—it shows a commendable spirit. Of course we must have prisms, and the men who crudely divide these in .5 Ds may still have seven, from .5 to 3.50, to use in glass corrections. There are two hundred and fifty-two combinations of these with the cylinders, four hundred and fifty with the sphericals, and fifteen thousand one hundred and twenty with the sphero-cylinders. The prisms in each of these may be turned in, out, up, or down for the simple little muscle troubles lately mentioned, or in combinations of vertical and horizontal deviations put at the proper oblique axis expressed in degrees. If these eighteen thousand and fifty-five different glasses, with their various positions, are not appropriate, there remain to considered operations upon the muscles and drugs affecting the eyes; and yet some men are criticized for turning to these before increasing the more than seven millions (7,685,960) of possible variations presented by the one hundred and three glasses above mentioned, including their combinations and the various axes of the prisms and cylinders. And these are for the correction of one eye; the number must be squared to show possible pairs of glasses.

Yet the extensive armamentarium of the refractionist has grown up for a purpose, and in response to a demand. Less than half a century ago, when the old theory of absorption of intestinal products as a cause of headache had led to little, the nervous theory to less, and the nose and the uterus were recognized as having an occasional and incidental connection with headaches, wonderful advances

* Astigmatism, simple, compound, irregular, and mixed, counted separately instead of grouped as before.

were made in ophthalmology, including glass corrections for visual purposes. Then it was regularly found that, even when the sight was improved properly, the glasses might cause headache, while at other times chronic headaches, which had previously resisted treatment, disappeared.

To-day the relief of headaches from eye correction is one of the clinical wonders of the age, and a necessity of modern civilization. The most ignorant fakir, and the "graduate optician," with a few lessons from an ignoramus, relieve some pain in this way, while the best of the ophthalmologists sometimes fail—even when the case seems clear, the eye conditions favorable, and the patient is not one of those who will neither use atropine, wear glasses, submit to operation, nor take any medicine suggested by a physician.

An eye specialist has little experience who has not had an opportunity to see over ten thousand cases of eye strain and headache in twenty years or so of practice. During the first five years patients with eye strain and direct head pains therefrom come to him, and he is pleased to find how successful his treatment is, without any worry about mathematical and physiological problems. At a later time his respect for his own opinion decreases, for now patients come to him to be cured of all sorts of headache, and are sent for a decision as to the probable origin of their trouble.

In the classification given some time ago we notice the occurrence of three forms of pain from the eyes; the first is a pain about the eyes, in the forehead and temporal region; this is exactly the kind of pain which occurs in two inflammatory conditions affecting the ciliary body, iritis and glaucoma. The vascular structures of the eye are often congested, but the pain may readily be explained by extension along sensory nerves, leaving the vascular explanation for exceptional cases; for the pain over the eye is deep, often in the orbit, and if there is tenderness over the trunk of the supra-orbital nerve this is not easily removed by eye corrections. In the latter case there is a history of some toxæmia from malaria, gout, or syphilis, given in the order of frequency, as an indication for a more rational and successful course of treatment. Gastro-intestinal causes occupy almost as indefinite a position as eye errors in this neuritis.

We now have a direct explanation for the most uncomplicated form of ocular headache without assuming, with a recent writer, that the irritation of the motor nerves sets up central irritation, which is conveyed down the sensory nerves. The difference between sensory and motor nerves still rests mainly upon the knowledge of an exactly opposite function to this, and it seems a long way to travel for a pain already waiting at the starting point.

The next characteristic pain from ocular causes is about the post-cervical region. Since there are two ciliospinal centres for vasomotor action and dilatation of the pupil in this region, it seems reasonable to suppose that there is a sensory connection from the eye to these centres. Some not entirely pleasant experiences have convinced me that deep, persistent basilar pain is rather a sign of arteriosclerosis, chronic nephritis, hepatic or cardiac changes, pachymeningitis or other brain involvement, than of eye strain. The "neck pain" of eye strain, however, seems naturally to belong to its excitant.

The other form of ocular headache mentioned was described as general. General headache from ocular causes is properly sub-divided into two forms; the first occurs in anæmic patients with low arterial tension, usually suffering from malnutrition and neurasthenia. Intelligent and unemotional patients describe it as follows: If the eyes are used fatigue sets in, followed by a dull pain about the eyes and the cervical portion of the spine; this becomes more severe with further use of the eyes, and extends upward into the head. Although considered general, it will be noticed that patients when describing this headache put their right hand upon the brow or temple in illustrating the local pain, and the left hand over the region of the left occipital lobe of the brain when they speak of the ache within the cranium; and when asked the reason of this, after some consideration, reply that the pain is more severe in these situations. The functionally stronger eye, usually the right, is regularly the seat of the most pain, as, like the stronger right arm, it comes in for the greater use; the left brain suffers more than the right from headaches for the same reason, and also because more directly affected through the circulation. The second sub-form of general headache from eye strain occurs in individuals with a family history of gout or chronic rheumatism, hay asthma, or something else which has to do with sudden vascular changes, or in subjects who change color readily with emotion; the headache attacks are severe, with somewhat irregular intermissions or remissions, and are accompanied by pallor, although I have seen no marked changes in the retinal arteries during the attack.

The classification of forms of eye strain and headache from which we started was intended to show that a distinct difference existed in the eyes which caused general headache and those causing direct neuralgias with extension along sensory nerves. We see that ciliary strain causes the latter, and disturbed equilibrium the former; for oblique astigmatism causes disturbances of equilibrium. After this has been sifted out from a mass of material, by dint of hard labor, we find it necessary to divide the general headaches according to constitutional differences, in order to explain that anæmic and neurasthenic patients have general headaches sometimes from strain of the organs of vision, peripheral and central.

Next we must explain other headaches as due to low arterial tension or vascular spasm and must even consider influences through the emotions; for how else comes the relief sometimes obtained from inadequate or improper eye corrections, or the distress caused by evidently appropriate ones.

So we are compelled, in order to explain certain phenomena connected with ocular headaches, to fall back upon that state which, described as "neurotic," conveys to a medical man a definite idea of an indefinite condition. Patients with eye-strain and headache belong largely to the neurotic class, and in many of them the only reason that the pain comes from the eyes is because these organs include that portion of the brain most exposed to mechanical strain and chemical irritation, and because there are more possibilities for worry and terror about their functions than those of any other portion of the body.

Many patients with eye-strain and general headache have a family history of inherited syphilis, epilepsy, or other nerve degeneration, as well as evidences of vasomotor peculiarities, and for me there is little doubt that certain of the muscular deviation tendencies, especially the vertical ones, are of paretic origin.

Neither is this condition which predisposes to headache a limited affair of local origin. The restless, excitable members of the Aryan race moved westward leaving the calmer, less nervous ones with each successive migration; so by a course of selection

by emigration, the most neurotic of all arrived in America, where they are suffering from eye strain and headache to an extent unknown in the East. The same thing happened with the eastern movement of the yellow race; the neurotic Mongols migrated to Japan; the less progressive ones stayed in Asia, and the Japanese now suffer greatly from eye-strain and headache, while in China such troubles are uncommon. And now, without dwelling upon the wonderful advances being made in modern civilization and nerve degeneration, let us leave the cases of headache which are purely ocular, and those partly ocular, where degeneration, malnutrition and vascular conditions which cause decreased blood supply enter into our calculations in variable degree.

Among the headaches seen by the oculist occur some, small by percentage among functional headaches, but large enough in number withal, in which the eyes have absolutely nothing to do with the pain.

There are three forms, excluding neuralgias from general causes which can usually be recognized by their alternation with other neuralgias.

The first is a headache which appears primarily or solely at the vertex and may be a mere feeling of pressure across the top of the head, or a severe and more extensive pain. It is due to anæmia or toxæmia. Only in the more severe or intermittent types is there a history of gout added to the usually clear history of stomach and intestinal indigestion. This headache follows the course of the general condition.

The second kind is similar to some forms of general headache due to eye strain. It may be, like the last form, persistent for days or weeks, and the patient usually is indefinite about the seat of the pain, describing it as in one or another spot at one moment then, soon after, as general. There are complaints about the eyes, and relief is demanded through their correction, although the case seems like one of incipient brain disease, and in some of these cases such disease does eventually develop.

The third headache not traceable to eye strain is that form called migraine, when that term is confined to a periodic headache with vomiting, usually hemicrania, hereditary, and of unknown origin. Headaches of this general type occur frequently from ocular disturbances of equilibrium, even with transient amblyopia and subjective sensations of light and color, and a form of hemicrania of a somewhat similar type has long been known as one among others due to nasal catarrh and obstruction. What distinguishes migraine from other headaches? It would seem that the sudden onset and severity, the definite history of heredity, and the regular periodicity of occurrence after an interval of complete abeyance, are, when combined, the most available diagnostic points. Yet eye errors are hereditary, and there is a familiar regular weekly headache which has been variously ascribed to nervous exhaustion, toxæmia, or eye strain, since it occurs mostly in men who have been somewhere Saturday night, and comes on after the Sunday morning papers are read. This tendency to regular periodicity is familiar to all, and Darwin in his "Descent of Man" writes: "Animals living about the mean high or low water mark pass through a complete cycle of changes in a fortnight. Their food supply will undergo marked changes week by week, and the vital functions of such animals, living under these conditions for many generations, can hardly fail to run their course in regular weekly periods. Now it is a mysterious fact that in the higher and now terrestrial vertebrata, as well as in other classes, many normal and abnormal processes have one or more whole weeks as their periods. . . . . [Many instances of such periodic processes might be given as the gestation of mammals, the duration of fevers, etc. . . . . .

Should the naturalists establish the missing connection between organic and inorganic life, we may be forced, for hereditary influences, to go back to the vicissitudes of some rock or stone during one of the glacial epochs; for periodicity, however, we need only go to our ancestors known at present as "marine animals resembling the larvæ of existing Ascidians."

How did the germs establish a periodic tendency? Did we all descend from this common ancestor, or did the microbes wait along the shore for the flowing tide to come in with *our* ancestors before attacking them?*

Headaches were from the first referred to the nervous system; yet the only marked advances in knowledge of their causation and real success in their treatment, since 1855, when Dr. Samuel Jackson referred with some scorn to what he called the "more or less" theory of the nervous fluid, have been made through the study of the processes of digestion or of eye strain; for the elaboration of the theory of nervous action into one of sensory discharges or nerve storms, to explain migraine, merely resulted in certain picturesque descriptions of the phenomena without working hypotheses. More recent studies of the effects of toxins upon the neurons point back to the digestive and circulatory functions as the essential consideration. This direct toxic effect is, of course, of great importance, and fits in well with studies of pathological headaches and those due to strain of highly organized and badly nourished nervous tissue. Yet toxins seem to produce remittent or intermittent forms of headache mainly by their effect upon the blood supply, and low tension or perhaps vascular spasm may alone account for attendant phenomena. Severe hemicrania occurs in some cases upon the side of the head corresponding to a ligated carotid, disappearing when collateral circulation is established. In the headache caused by alcohol, the poison is absorbed and produces stimulation and high tension, yet the headache does not appear until weak heart action and low arterial tension are present while nicotine, causing low tension, brings on headache with the absorption of the poison. Stimulants, especially strychnine, are efficient in treatment.

Headaches occurring with menstruation set in, with attending retinal exhaustion, with most severity after a free flow of blood, accompanied with facial pallor, and migraine usually shows the same vascular condition, although a flushed face may usher in or precede the attack.

Among the puzzling things in connection with these

* If the origin of migraine is but ill explained by a comparison with thunder storms, the matter is little advanced by referring the question of periodicity to a time when headache was unknown, since heads were yet to be evolved. Primitive man is supposed, like savages of to-day, to have periodically gorged himself with food, as he happened to obtain a supply. We know that at a later period in the world's history, chiefs sallied out with their clans for plunder when the tribal larders needed to be replenished, and upon their return indulged in drunkenness and gluttony; "and there is nothing sure but the morning head." Transmisson of such traits to posterity, with the constitutional, effects produced by "errors of diet" of this nature, continued through many generations, account singularly well for a predisposition to migraine. The view that migraine is a sort of transmitted *katzenjammer* is supported by many points of similarity, but if it were positively known to be true, it would serve no practical purpose. A recurrent period, if approximate of the right duration for any process of function, would not, when once gained, be liable to change; consequently it might be transmitted to almost any number of generations.

facts is the action of the coal-tar products in relieving headache, since they produce pallor and apparently a less active supply of blood; neither a vascular nor an antitoxic action would seem to account satisfactorily for their effect upon the pain.

Leaving out pathological headaches, including those of nasal obstruction, treatment should be directed toward correcting the eyes and improving nutrition; uterine treatment is here included with the latter, for headaches described as uterine are only those of anæmia, toxæmia, or eye strain, as the same forms occur from ocular or vascular causes in men as well as in women.

Although headaches from the eyes are usually worse at night as compared with most others, too much reliance should not be placed upon this point. Headaches from eye strain can not be diagnosed by the chamber of the headache alone, but by the presence of the eye strain as well, and the establishment of a coincident relation.

Perhaps the very best rule yet given by which the headache of eye strain may be diagnosed was that laid down by Donders. It is, slightly modified, that when anybody is seen to frown, squeeze the lids together and rub the forehead upon using the eyes, eye strain is present and by a little elasticity this will serve for local pain and general headache caused by refractive errors and divergence tendency or exophoria. The headaches of vertical tendency or hyperphoria are harder to connect with eye strain, but since patients with hyperphoria tip the head sideways upon attempting to see clearly, and patients who tip the head toward either shoulder when looking at objects usually have hyperphoria, we have a diagnostic sign of that condition.

The more difficult diagnosis of headache from convergence tendency or esophoria yet remains. If the patients have sick headache from theatre-going, visiting picture galleries, railroad journeys, bicycle riding, or the like, esophoria should be suspected. If they develop headache regularly after continued fixation of distant objects under different atmospheric conditions, esophoria may be diagnosed. These rules apply to cases with no eye correction, or to those with improper or insufficient correction.

And what are we to do with the well nourished, rushing, flushing, blushing one, our best friend or our worst enemy, whose pains travel about like coins of a juggler, in at the head and out at the elbow? Our responsibility is great, for at a word we may transport a human being from the enjoyment of a psychophysical flower garden into the middle of a great desert, and the return journey may be very difficult.

As we rise in the social scale, we see such an increase in these troubles that we are absolutely sure that they arise from the possession of too much money, and the greatest of medical indications is "removal of the cause!" We are now approaching high art where only a few geniuses in our profession seem properly proficient.

After all, success in the treatment of eye strain or gastro-intestinal disorders may be "the gift of fortune," but ability to handle the emotional element "comes by nature."

118 East Seventy-Second Street.

Japanese Dentists perform all their operations in the drawing with the thumb and forefinger of one hand. The skill necessary to do this is acquired only after long practice, but when once it is obtained, the operator is able to extract half a dozen teeth in about thirty seconds, without once removing his fingers from the patient's mouth.

THE TAMPON IN GYNECOLOGICAL THERAPY.

By MAXWELL BENJAMIN, M.D.,

New York,

Attending Gynecologist to the Lebanon Hospital, in charge of Department; Clinical Assistant in Gynecology at the New York Post-Graduate Medical School and Hospital.

In writing this paper it is in main the object of the author to call the attention of the general practitioner to a method of treatment which appears to be a somewhat neglected art.

There is a class of gynecological patients which find their way into the office of the family physician and in which surgical measures are not always indicated. It is in these cases that the proper application of a vaginal tampon is sometimes productive of excellent results. It should be noted, though, that each case is a study in itself, and that different conditions require variations in the manner of treatment.

In too many instances, physicians think all that is necessary is to insert a tampon, made of any kind of material, with the patient in any position whatever, and then are disappointed if the results are not always good.

It is not the intention of the writer to hold that tamponing, even if properly done, can replace radical measures, but some patients meet the idea of an operation, no matter how slight it may be, with such abhorrence that the physician is tempted to try to alleviate their suffering with less heroic treatment.

Then it is that the tampon comes into use, and the relief that its proper application produces is surprising as well as gratifying. There is also a class of cases in which some functional disease, such as diabetes, nephritis, or endocarditis, contraindicates the administration of an anæsthetic, and the tampon then presents itself as one of the methods of treatment to which the surgeon must resort.

Material.—As regards the materials that are commonly selected and employed for this purpose, I may state that some substance which is non-irritating to the mucous membrane, which possesses good draining properties, is easily introduced and removed, is soft and retains its resiliency for a great length of time, even when wet, should be used. The materials which possess the above qualities to a greater or less degree are cotton wool, and gauze.

The two preparations of cotton, namely the absorbent and the non-absorbent, have each their merits and their objections. Absorbent cotton is invaluable for the application of fluid medicaments, with which it readily becomes saturated; but when the excess of fluid has been expressed we have a hard mass of cotton, which does not favor drainage.

It should therefore be noted that when this material is used, and when the excess of medicinal fluid has been expressed, the tampon should be spread out flat and its fibers separated by the fingers of the physician or nurse. This will relieve its hard and impervious condition and cause it to assume all the properties for which it is intended. With these precautions we are sure that there remains sufficient room for drainage, and this important quality will still further be facilitated by the saturation of the tampon with the secretions of the vagina and uterus, which also tend to convert it into a soft mass.

Non-absorbent cotton may be used where an antiseptic or astringent powder is to be applied. In flexions, versions, and mild forms of prolapsus it may be employed for the mechanical effect. I also use it as a means of preventing the medicinal fluid, held by an absorbent tampon previously introduced, from escaping and soiling the patient's linen.

Wool probably possesses more objections than any other material. It is rather more expensive than

cotton, but its use will give both physician and patient such satisfactory results, as fully to compensate for its additional cost. It is naturally soft, allows for drainage, and retains its resiliency for a longer period than cotton. The ordinary wool, or lamb's wool, it should be noted, has the property of working its way into the mucous membrane of the vagina, and if introduced dry and left for twenty-four to forty-eight hours, it cannot be removed without injury to the mucous membrane and severe pain to the patient. The tampon should, therefore, previous to its insertion, be covered with vaseline or other emollient. If the operator purposes applying an antiseptic or astringent powder, the tampon, after being covered with vaseline, may be rolled in the powder and then introduced.

Another method of averting the evils that may be produced by a wool tampon, has been described by R. T. Morris, and is perhaps the most satisfactory way in which to apply a vaginal dressing in selected cases. The wool is covered with a layer of absorbent cotton, which becomes saturated with the medicament, while the nucleus of wool within gives the tampon the required degree of elasticity or resiliency and serves also as a perfect medium for drainage. The ends of the tampon are not covered with cotton, but are left free so as to prevent the packing from slipping. Morris states that the loose ends should be left dry, but I have been in the habit of covering the ends with a small amount of vaseline, as I believe that even this small exposure of wool will cause irritation of the mucous membrane. Waldo recommends Australian wool as the best material for vaginal tampons. He states that "it is fine and non-irritating, is hygroscopic and retains its resiliency when wet. Combed wool is much better than uncombed because no short pieces are left to irritate the mucous membrane."

Gauze is used by many gynecologists in numerous disorders. Personally I never use it, except as a means of checking hemorrhage such as that which arises from an ulcerated carcinoma, or in cases of misplacement of the uterus for its mechanical effect.

Size.—The size of the tampon is an important feature. It is better to use a few small tampons than one large one, for the reason that because of its bulk, the large tampon cannot be easily manipulated and applied to the exact portion of the vagina or uterus that it is the object of the surgeon to treat.

The cotton tampon that I employ is made as follows: A piece of cotton five inches long and three inches wide, is folded, not rolled, into four thicknesses, and a double thread, about six inches long, is tied about its center. The tampon thus becomes about one and one-quarter inches wide. Rolling the cotton causes the center of the tampon to be hard and robs it of its absorbent properties.

The wool tampon is made the same as the above, and then covered with a layer of absorbent cotton about one-quarter of an inch thick, in this method is used. Gauze tampons are made by means of a piece of gauze eight inches square, folded four times and impregnated with the medicament. They should be packed into the vagina in an accordion-pleated form. Among other materials that I might mention, and that have been used but are more or less abandoned, are jute, charpie, and wood wool.

Application.—In the application of a tampon, the position of the patient is important. For most purposes Sims' position is the one selected. It possesses several advantages. Upon the retraction of its posterior wall, with a Sims speculum, the vagina becomes ballooned out with air, and there is presented to the operator a full view of the vaginal walls and the cervix uteri. The distension thus produced is not so great as that occurring in the knee chest position, and the possibility of overpacking the vagina is thus overcome. In backward displacements of the uterus, however, the genu-pectoral posture has the advantage, for the uterus is thrown forward, and the packing may then be placed in the posterior fornix, thereby preventing the organ from again assuming its malposition when the patient arises from the table. Many operators prefer the dorsal posture. The field thus presented is limited, although this position is best during the digital examination. For office work, when the operator may not have the advantage of an assistant, the dorsal posture presents many inducements, for with the use of a bivalve speculum the cervix can be clearly brought into view, and still the operator has the use of both hands.

If the Sims' position has been selected, after the posterior vaginal wall is retracted with a Sims' speculum, a vaginal depressor to retract the anterior vaginal wall, will still further assist in bringing the cervix into view. A pair of straight uterine forceps is then seleceted, and the medicated tampon is seized longitudinally at its center. Care should be taken that the ends of the forceps do not project beyond the tampon, for injury might thus be inflicted upon the mucous membrane of the vagina, or upon the cervix with which the forceps would come in contact.

The tampon is then placed in the portion of the vagina in which it is indicated, be it in the anterior, posterior, or lateral fornices, in direct contact with the os, or encircling the cervix. The forceps is then held against the packing, so as to prevent any displacement which even the gentle withdrawal of the speculum might cause. After the speculum is thus removed, the forceps is also withdrawn. The packing should remain in place for twenty-four hours, after which it should be removed either by the patient or the physician. It is an important matter to enlighten the patient upon the fact that a tampon has been inserted, for there are a number of cases reported in which the patient failed to return, and the packing undergoing putrefaction, produced severe sepsis. Beckwith reports the case of a woman in whom a tampon had been inserted by a midwife twenty-nine years previously, without the patient's knowledge, and which was removed with difficulty. The tampon in this case had become encrusted with a shell of lime salts, and was taken out piece-meal and at intervals, because of the hemorrhage that its extraction caused.

It will be found that the removal of the packing is facilitated by retracting the perineum with the finger, and by pulling on the thread downward and backward. All pressure should be avoided, and if any difficulty is experienced, the physician should not hesitate to introduce a speculum and remove the packing by means of forceps. A hot vaginal douche should then be administered, when a second application may be made if necessary.

Purposes.—The purposes for which tampons are applied are two-fold, namely, for their (*a*) medicinal and (*b*) mechanical effects. The medicament chosen may be applied for the relief of pain, or to produce counter-irritation, absorption of inflammatory products, or contraction of relaxed tissues. Glycerin is the best adjuvant to other drugs. It is hygroscopic and will assist in the reduction of an enlarged uterus. It tends to soften a hardened os uteri and also aids to reduce over-distension of the blood vessels in the organ.

In erosion of the cervix, a tampon carrying a twenty-five per cent. solution of ichthyol in glycerin, will, beside its germicidal action, cause a desquamation of the epithelial cells of the cervix. This I have seen followed by a regeneration and the return of the cervix to its normal condition.

Chronic endometritis and parametritis will be benefited by placing beneath the cervix a tampon of boroglycerin (forty per cent.), or ichthyol in glycerin (fifteen per cent.). The packing will also exercise the mechanical effect of elevating the uterus, thus improving its circulation. If after several applications there does not appear to be any improvement, this treatment should be discontinued, and some radical measure, *e. g.*, curettage, performed. It is not my intention to convey the impression that I believe that palliative therapeusis of this nature will always replace the more positive remedy of curettage. Chronic metritis may be treated in a way similar to that described under chronic endometritis.

Hemorrhage which has its source from the vagina or cervix is usually controlled by applying a hemostatic such as tannic or gallic acid or the new preparation, suprarenal extract. Gauze is easily impregnated with these powders, and can then be packed tight into the vagina with the powder in direct contact, if possible, with the bleeding point. In inoperable tumors accompanied by a foul discharge, such as fetid carcinoma, a mixture of equal parts by volume of tannic acid and iodoform, will, in addition to its styptic effect, act as a powerful deodorant. Should the hemorrhage not be controlled by the above measures, gauze soaked in perchloride of iron, with or without the addition of tannic acid, may be used to pack the vagina. The gauze thus applied forms a hard and impenetrable mass, and is usually certain to control the most obstinate bleeding. Care must be taken, though, to protect the patient's linen or the bed clothes from becoming soiled by the inky fluid which this combination forms.

In subacute salpingo-oöphoritis, after the section of vaginal mucous membrane surrounding the inflammation has been painted with tincture of iodine, a tampon of boroglycerin or ichthyol in glycerin (twenty-five per cent.) should be placed against the tumor. The iodine is applied by means of a piece of absorbent cotton wound about a uterine applicator, and care must be taken to express the superfluous iodine, so that none but the required part of the vagina will be painted. The same treatment will be found efficient in pelvic peritonitis where the action of the medicated tampon will loosen the adhesions caused by the inflammatory products.

Vaginitis and vulvitis may be treated by applying a solution of silver nitrate directly to the inflamed parts, and then holding the surfaces apart by a tampon impregnated with boracic acid. A two per cent. solution of silver nitrate is used at first, and the strength is gradually increased until a ten per cent. solution is reached. After the swollen parts have been well rubbed with the silver nitrate, the tampon is introduced. The silver has a germicidal action, and the boracic acid assists in modifying the inflammation.

Lusk recommends the tampon in menorrhagia, and my experience with it in this condition has led me to agree with his conclusion that "the practically complete repression of the menstrual flow is absolutely harmless." The best method to employ is that of Marion Sims, which in the words of the author is as follows: "Wads of cotton of suitable size, soaked in carbolized water, and compressed into the form of flattened discs, are applied firmly to the vault of the vagina. The Sims' speculum is used and the pads should be placed with the flattened surfaces in a transverse position rather than parallel with the vagina. The packing is stopped at the urethro-vaginal septum. They should be removed at the end of twenty-four hours, the vagina irrigated, and a fresh packing applied."

In cases in which this treatment is followed by unfavorable symptoms due to the repression of the flow the packing may be applied after the patient has menstruated for two or three days, and good results will be obtained if this treatment is even carried out in the intermediate periods.

The mechanical action of tampons has been referred to in the discussion on vulvitis and vaginitis, in which we have seen that the addition of a medicinal agent causes them to assume a two-fold function.

In hemorrhage, in addition to the properties already cited, Abbot states that the tampon acts in three mechanical ways: first, to compress the afferent arteries and the os uteri; second, to mechanically entangle the fibrin and form a blood clot; and third, to form a dam to the outflowing blood.

In prolapse, version, and flexion of the uterus, the proper introduction of a tampon will sustain the uterus at a higher level and improve its circulation. In version of the uterus, the patient should be placed in the knee-chest posture, thus throwing the uterus forward, after which the insertion of a tampon in the posterior fornix of the vagina and encircling the cervix in a semicircular fashion will hold the organ in its normal position.

Flexions should be treated with the patient in the dorsal position, and with the tampon in the anterior fornix around the cervix as described above. As these two conditions are usually accompanied by endometritis, the tampon should be saturated with a solution of ichthyol in glycerin, as stated in the discussion on that affection.

Cystocele and rectocele may be relieved by introducing a tampon around and encircling the cervix, and then a second, and if necessary a third, against the os uteri. This relieves the patient from the dragging pains due to lack of support of the uterus, and removes the cause of frequent and painful micturition, to which women in these conditions are subjected.

In cases of miscarriage prior to the fourth month, a tampon serves as a useful adjuvant in terminating the premature labor. This is produced by the pressure of the uterus during expulsive efforts against the tampon, which serves to relax the os uteri. The tampon used in this case is preferably of antiseptic gauze impregnated with boracic acid.

When uterine packing is indicated, a vaginal tampon of gauze will serve as a reinforcement, and as an aid in diagnosis, through the discharge which clings to it, it will be found invaluable.

Many women in whom a pessary causes great discomfort will, after several introductions of a soft cotton or wool tampon, bear the pessary very well.

The Medical Supervision of School Children.—J. Cassel advocates the plan of having regular medical examination, to be seconded by such special treatment as may be needed, a part of the public school system. Weak-minded children could then be subjected to such modes of teaching as would be best adapted to their mentality, and, in particular, the eye and ear specialists would find much useful work to do. The interchange of views between pedagogues and physicians would result in the development of ideas valuable to both professions, while the children themselves would be immeasurably benefited.

LATENT PULMONARY TUBERCULOSIS.

By CHAS. R. UPSON, M.D.,

WATERBURY, CONN.

I use the term "latent" in this paper to indicate the unsuspected presence, in a large class of cases, of pulmonary tuberculosis, the symptoms of which are so ill-defined that the patient, and too frequently his medical attendant as well, fail to appreciate their true import. It has been estimated by other writers on this subject that not one case in fifteen of consumption is diagnosed in an early stage, but an extended study of this class of cases justifies me in placing a much lower estimate on the number of early diagnosed cases. It is my belief that fifty per cent. of our population are or have been infected with pulmonary tuberculosis. The disease is to a large extent latent, and an early diagnosis is not only the great essential to its successful treatment, but is of the utmost value in preventing the spread of the disease.

Illustrative of the prevalence of unsuspected cases of pulmonary tuberculosis, I would call attention to the following brief summary of one hundred and ninety-seven cases of patients who have consulted me for other than lung affections, whom I found to be tuberculous, and yet none of whom suspected the presence of the disease. These cases were classified as follows:

Naso-pharyngeal catarrh	68
Hypertrophic rhinitis	30
Hypertrophy of the tonsils	35
Purulent otitis media	25
Chronic catarrhal otitis media	18
Mucous polypi	12

It will be noted that I have—for obvious reasons—excluded from the above classification all cases in which cough was a prominent symptom. None of these patients had previously been examined for lung trouble nor had any of them, as I have already stated, suspected the existence of such a condition. Although in quite a number of cases the patient had recently consulted a physician regarding certain persistent ill feelings, in no case had an examination of the lungs been made. A considerable number of these cases had been labeled "malaria", that indefinite term which is so often used by careless practitioners in hastily-made diagnoses.

These cases may be most conveniently studied under the following heads:

Sex—115 patients were females and 82 males.

Age—Under 10 years, 12 (8 females and 4 males); between the ages of 10 and 20, 38 (27 females, 11 males); between 20 and 30, 45 (17 females, 28 males); between 30 and 40, 63 (38 females, 25 males); between 40 and 50, 35 (25 females, 10 males); between 50 and 60, 4 (all males).

Family and Personal History—Both the family and personal histories were good in 145 cases. In 52 cases the family history showed a susceptibility to disease. The personal history in 100 cases was good. In 97 cases there was a history of frequent or occasional attacks of indigestion, diarrhœa, or constipation; 5 patients acknowledged having had syphilis; 5 had met with accidents—falls, blows on the chest or back—since which there had been a slight "shortness of breath" on exertion.

Home Environment—So far as I could learn the home environment in 90 cases was satisfactory. In 78 cases the patients had lived or worked with consumptives; 48 cases were among boarders in the poor classes of boarding-houses, where the hygienic and other conditions were far from satisfactory.

Occupations—Students (including school children), 25. Persons of leisure, 12. Factory operatives and machinists, 90. Clerks, book-keepers, and stenographers, 15. Dressmakers, 5. Professional men and women, 10. Farmers and milk-men, 3. Commercial travelers, 6. Housekeepers and servants, 15. Unclassified, 16.

Inspection—There was little in the appearance in 50 of the cases to call attention to the existence of lung disease. In 125 cases the eye conditions were more or less noticeable, showing an exaggerated brilliancy, or dilated pupils, or both; in 20 cases the pupils were unequally dilated.

There was pallor in 63 cases. In 72 cases there was abnormal chest development. Unequal chest expansion was noticeable in many cases in which but one lung was involved. Close inspection and careful measurements of the chest during forced respiration will frequently show diminished expansion of the affected side, even in cases presenting but few physical signs.

Physical Signs—Exploration of the chest gave the following indications of pulmonary tuberculosis: The percussion note was in 148 cases a trifle duller than normal. In 28 the dulness was more markey and the percussion note was higher. The respiratord murmur in 142 cases was lowered in intensity; in 29 it was increased and pitched higher, with, in many cases, a jerky or "cog-wheel" respiration. In 116 cases, in some of which it was difficult to detect dulness, there was in the posterior apical region a noticeable transmission of the heart sounds. Prolonged tubular breathing and fine râles on forced coughing were noticed in 115 cases.

Temperature—There was in 118 cases a slight rise in temperature of from 0.8° to 1.6° F. In 38 cases, in which the temperature was normal, exercise to the point of fatigue caused a rise of from 0.9° to 1.9° F., leaving but 41 cases in which the temperature was normal under all conditions. When possible, the afternoon temperature was taken daily for a considerable period after the completion of the digestive process. A sub-normal morning temperature was found in 17 cases.

Respiration and Pulse—There were increased respiratory movements and rapid pulse in 105 cases, exclusive of the 33 cases in which there was a rise of temperature following fatigue.

Appetite, Digestion, Assimilation, and Weight—In 125 cases the appetite was more or less impaired or capricious. In 97 cases, the digestion and assimilation were imperfect and accompanied by a loss of from 3 to 13 pounds in weight.

Vitality—There was an admission in 132 cases of an increasing sense of fatigue following mental or physical exertion. Most of the patients mentioned a general "tired feeling," especially during the early morning hours, notwithstanding a good night's sleep.

Cough and Expectoration—Slight cough or hacking on assuming a reclining posture or on arising in the morning was present in 130 cases with little or no expectoration other than that of catarrhal matter.

Dyspnœa—"Shortness of breath" on exertion had been noticed in 105 cases. In 10 cases they "got out of breath easily." The remaining patients would not confess to any difficulty in breathing. In several cases the dyspnœa was out of proportion to the extent of lung involvement, but none of these cases showed any signs of heart disease.

Hæmoptysis—12 patients admitted having "spat up blood." Two of these—single women, aged respectively 19 and 30 years—had been "raising blood," one for 3 and the other for 5 months, at each catamenial period—the catamenia being normal.

Chest Pains—Pleuritic pains of varying intensity had been present in 90 cases.

Night Sweats—In but 26 cases had night sweats

been a prominent symptom; in 4 instances they had occurred in patients presenting the fewest physical signs. In 72 cases the patient had noticed occasional night sweats—in many cases, however, so light as hardly to attract attention.

Pharyngeal and Laryngeal Symptoms—In a large proportion of the cases the pharyngeal and laryngeal mucous membranes presented a more or less congested appearance. In some cases the membrane was decidedly pale, while in others there was pallor of the pharyngeal mucous membrane with more or less marked local congestion of the arytenoid region.

Other Symptoms—Intestinal indigestion was present in 95 cases, accompanied by occasional attacks of diarrhœa in 38. In 53 cases there was constipation. A coated tongue was present in 106 cases, and more or less headache was complained of in most of them. Many of the patients believed their general ill feelings to be due either to "chills," "dyspepsia," or "malaria"—the latter being the favorite self-diagnosis.

Leaving the reader to make his own deductions and draw his own inferences from the above reported cases of latent tuberculosis, I will simply call attention to the frequent occurrence in these case of certain subjective and objective symptoms, which, when present, are sufficiently significant of the initial stage of the disease to call for a thorough physical examination of the patient. Whenever the disease is diagnosed the physician should, for the protection of the patient, his associates, and the community, advise the former or his family of the fact.

Dr. Von Ruck[1] in speaking of the causes which are responsible for the frequently tardy recognition of pulmonary tuberculosis, says: 'In instances where a physician is consulted and makes a correct diagnosis he is liable to be discredited either by the patient, when an intermission of the symptoms takes place, or by his neighbor practitioner who may have failed to appreciate the true state of affairs; under all circumstances it will be found difficult to convince the average patient or his interested friends that the slight symptoms of general malaise, loss of appetite and strength, or decline of a few pounds in weight, mean really the onset of so serious an affection as pulmonary tuberculosis, and though we may succeed while the symptoms last, their disappearance makes the interested parties again sceptical, since their ideas of tuberculosis are derived from what they have observed in cases of consumption that have reached a progressive or downward course."

Every physician who has given the subject careful study will readily admit the great prevalence of latent pulmonary tuberculosis, which will doubtless suggest to him the urgent necessity for the institution by the profession and public authorities of active measures for checking its insidious advance.

It is largely through ignorance of the true significance of these early subjective symptoms and the apathy of the lay population that the disease is permitted to gain such a firm hold on its victim. The remedy, to my mind, is a simple one and easily within the reach of every municipality. I refer to the publication and general distribution by boards of health of literature describing the early subjective symptoms of pulmonary tuberculosis and the necessity, whenever these symptoms are noticed, of an examination of the lungs. The circular should, furthermore, explain that while the disease is largely curable in this stage it will, if neglected, rapidly advance to the incurable stage, rendering the victim a source of danger not only to himself but to others.

Persons thus instructed in the dangers incident to their condition would, I am positive, early seek medical advice, and, if the physician failed to make it would insist on an examination of the lungs.

MEDIATE PALPATION,*

By E. W. WHITNEY, M.D.,
SALT LAKE CITY, UTAH.

In matters pertaining to physical diagnosis much depends upon habit and education. Often have I been astounded at the ease and rapidity with which certain of our colleagues have proclaimed grave pulmonary and cardiac lesions by a hasty pressure of the ear upon a chest enveloped in thick flannels and a starched shirt, or have declared those organs in a condition of perfect and natural health.

Often have I been sceptical as to the accuracy of the result, and sometimes the thought has forced itself upon me that the declaration was based more perhaps on the clinical history, state of nutrition, and physiognomy, than on a true analysis of the respiratory and circulatory data which are usually recognized in detail and fully only by a careful, painstaking, and intelligent research.

The senses vary in animals, and so some diagnosticians may have most acute hearing, and be able to recognize broncho-vesicular breathing at a bound, or to locate a cardiac murmur, audible to the ordinary clinician only after physical exertion on the part of the patient (as hurriedly ascending a flight of stairs), conjoined with quiet and the use of a favorite stethoscope. Many variations of this last instrument—the stethoscope—have been presented to us since we became wedded to the one we started with and perhaps still retain—as in my own case. There have been large bells, made larger by rubber overcoats, small bells, etc. It is not volume of sound, however, that we want in a stethoscope, but differentiation, or one that enables us to recognize the quality of the tones reaching our ears.

We can detect the sharp crack of a rifle and the boom of a cannon if we can but just hear them, and the fog siren when barely audible above the sound of the waves

The object, however, of this brief communication is to call attention to a manner of intensifying vibratory thrills in the employment of that old and familiar method styled palpation, as used to detect vocal fremitus, a bruit, frictions, crepitus, or rales, or any vibratory thrill perceived by the tactile nerves. The quality of these various signs is usually so definite and distinct that an increase in volume does not obtund its recognition.

The modern phonendoscope is to many an excellent instrument, and in skilled hands elicits the evidence sought. I have recently found, however, that not alone in auscultation do its merits lie, but also in its ability to emphasize and determine the vocal fremitus and all vibratory thrills brought to our cognizance through the tactile sense.

A short time since, when I first employed it in this method of examination, which perhaps might be styled "mediate palpation," the result was so brilliant that a day or so later I brought it to the attention of a friend, an adept in physical examination, and it is through his suggestion that I present this subject to the Society this evening.

The method of use is as follows: The phonendoscope is placed upon the chest, as is usual for auscultation, and then after the rubber tubes are removed, the palmar surface of the hand is laid upon it and receives the vibrations which have been reduplicated by passing through the instrument. Its action is akin

*Read before the Salt Lake County Medical Society, April 22d, 1901.

to that of a sounding board, delivering the result, however, to the sense of touch instead of to the auditory apparatus. One instrument can be shifted from one side to the other, or two can be used, one for each palm.

Any good conductor of vibration may be used, and I have tried several, but the phonendoscope does excellently, and if one has it, he need look no further at present, as it fulfills in this way a double office—namely, that of auscultation and mediate palpation.

To determine the presence of fluid or air in the pleural cavity is usually not difficult, and yet at times the examiner is not without some doubt, and if any detail of examination will throw additional light upon this frequent lesion, it is worthy of employment.

To detail all the conditions in which a vibratory thrill is felt, in greater or less volume than natural, would be an unnecessary labor, as fremitus, crepitus, and frictions are well understood by all. In tuberculosis, pneumonia, pleurisy, fluid exudates in the pleural cavity, pneumothorax—in fine, in all pulmonary lesions, fremitus is a valued sign.

Bony or ligamentous crepitus, in a difficult case, would, by this method, be accentuated. Hydatid fremitus would be made plainer.

I have in mind an instrument with diaphragms, on the order of the phonendoscope, for this special purpose.

The Treatment of Accidents Under Chloroform.—A. Wilson states that the indications for treatment are threefold; to remove the anæsthetic-laden air from the lungs, to encourage the flow of blood to the nerve centers, to stimulate the circulation and respiration. The various methods suggested for the attainment of these ends may be grouped into five classes: 1. External applications or procedures which, under normal conditions, excite reflex respiratory efforts, such as (*a*) cold or hot affusions to chest and face, Corrigan's button to epigastrium, hot sponge to perinæum, etc.; (*b*) rhythmical traction on the tongue, and dilatation of the sphincter ani. 2. Direct mechanical or electrical stimulation of the heart by intermittent pressure, rapid percussion, faradisation, acupuncture, etc. 3. The mechanical performance of natural functions, as artificial respiration with or without tracheotomy. 4. Measures of a mechanical nature designed to counteract the effects of failure of the circulation, by raising the general blood pressure, or causing the determination of blood to the vital centers—*e.g.*, the dependent position of the body, rectal enemata, transfusion, compression of abdomen, artificial respiration, curtailing the area of the circulation by bandaging the limbs, etc. 5. Drugs, introduced subcutaneously or by inhalation, which have the power of stimulating the depressed nerve centers—ammonia, nicotine, strychnine extract of suprarenal capsules, etc.—*Medical Chronicle.*

Diaphragmatic Hernia.—C. A. Parker says that diaphragmatic hernia is of fairly frequent occurrence; the diagnosis is more rarely made than in almost any other known surgical condition, being limited to two per cent of the cases. Absence of a sac is the rule, it being present in but ten per cent. of all cases, and in only about one per cent. of traumatic cases. Stab wounds are usually on the left side, because of the desire of an adversary to inflict injury on the heart side, and because it is the side naturally opposed to the stroke from an opponent's right hand. The contents of the hernia are most frequently omental, but may include almost every solid and hollow viscus in the abdomen. A complicating intercostal hernia is not infrequent, having occurred in two of the writer's five cases. Though many of the congenital and acquired lesions of the diaphragm are so extensive as to be quite incompatible with life, yet gross defects in its structure with dislocation of many important viscera, may occur with little or no disturbance of health. The diagnosis is aided by the presence of local scars or lesions directing attention to the diaphragm. Skiagraphy may also be of value. The immediate danger in large wounds of the diaphragm is due to injury of adjacent viscera; the remote danger, from contraction of the opening and constriction of the contents, is greatest in small wounds. Spontaneous cure may result from contraction of the orifice and atrophy of the contents composed of unimportant structures. The treatment is surgical, and is limited to a small percentage of cases, on account of (*a*) the infrequency of diagnosis, (*b*) severity of gross lesions and symptoms, and (*c*) inaccessibility of the part injured. In the examination of all wounds in range of the diaphragm, the possibility of injury to that muscle should be remembered, and all wounds in its structure should be closed at once, if possible, to prevent the development of hernia.—*Medicine.*

Recovery from Cerebro-Spinal Meningitis.—E. F. Trevelyan reports two cases. The first case was that of a boy of sixteen years, who complained of headache and vomiting. Three days later a swelling appeared on the back of the neck, followed by labial herpes, retraction of the head, and some loss of power in the legs. The pupils were equal, and reacted to light. The lad was delirious at times, and passed his urine in bed. A diagnosis was made of a diffuse meningitis. Iodide of potassium was given, but had to be speedily discontinued. On the thirteenth day, the swelling on the back of the neck was incised, and two ounces of pus evacuated from the deep muscular planes. The disease lasted fifty days in all. Its later stages were marked by temperature running intermittently (it had been 102° F. during the first two weeks), and gradually becoming normal. There was never any recognizable pneumonia, endocarditis, or other primary focus of disease. The second case occurred in a girl of fifteen years, and was ushered in with headache and severe and repeated vomiting. The neck was rigid, and the head retracted. On the fifth day the girl was comatose and unable to swallow. The symptoms varied in severity from time to time, and covered a period of about six weeks. From that time on, the patient steadily gained. There was no otorrhœa. The author has nothing new to add concerning treatment. He is not in favor of spinal puncture, which he believes to have very little to recommend it. He is inclined to believe that the only hope of a satisfactory treatment lies in orrhotherapy.—*Medical Chronicle.*

Some Points of Practical Importance in the Symptoms and Treatment of Acute Pneumonia.—R. H. Babcock calls attention to the fact that we may have a scattered exudate not large enough to give the classical signs of dulness, etc., but comprising, in the aggregate, considerable lung tissue. The infection in these cases is often intense. Cyanosis is present, and due to paralysis of the vasomotor centers in the spinal cord, being followed by heart weakness, secondary to this vasomotor paresis. The temperature in the axilla may be even subnormal, while the thermometer in the rectum will show considerable elevation. Thus, in one case, the axillary temperature was only 97.6° F., but the rectal temperature was 102.1° F. For such cases Babcock is disposed to rely on strychnine hypodermically, one-thirtieth to one-twentieth grain every two hours, or, in urgent cases, hourly. Valerianate of caffeine, in grain doses, may be given in the same manner every two hours. Toxic influences can be combated by the use of the decinormal salt solution, both by the rectum and under the skin. Venesection to the amount of sixteen to twenty ounces is also of service. As long as the blood is dark, it should be allowed to flow, but when it becomes red, it is evidence that enough has been withdrawn. Oxygen also finds, in these cases, a proper employment.—*Medicine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, July 20, 1901.

THE SUPPRESSION OF THE MOSQUITO.

SINCE it has been concluded more or less definitely that, in addition to being the chief if not the only means of propagating malaria, mosquitos are responsible for the dissemination of yellow fever, an unrelenting war of extermination, if possible, has been declared against the anopheles claviger and culex fasciatus. The difficulties in the way of a complete extermination of these two species are, however, so great, that general satisfaction will be given if only measures can be devised to reduce appreciably the numbers of the parasite-conveying insects, especially in tropical regions now largely frequented by white men. It has been shown already, that is so far as malarial fever is concerned, that protective measures—such as rendering the interiors of houses inaccessible at night to mosquitos and compelling workmen on night duty to wear cowls—are to a large extent effective.

Nevertheless more radical and wholesale methods than these are called for, and Mr. L. O. Howard of the Department of Agriculture, at Washington, in a book recently published,* declares that he sees no reason why the task of exterminating mosquitos altogether should be looked upon as impossible. While perhaps a large number of those versed in the ways of mosquitos may be inclined to regard Mr. Howard's views as somewhat unduly optimistic, yet such opinions proceeding from so eminent an authority are worthy of respectful consideration. Colonel Giles, a well known entomologist, serving in the British Army Medical Corps in India, speaking of the anopheles says: "Far from being as we have been led to expect confined to a few marshy pools of moderate size, they are omnipresent and seem to be capable of developing in water of very varying degrees of purity." Anopheles Rossii is in fact what Ficalbi would speak of as a "foveal" and not a "paludal" or even "sub-paludal" species. A consideration of these few facts makes it therefore self-evident that the task of extirpating malaria by the systematic treatment of mosquito-breeding places with larvicides, is by no means so simple as it was hoped it might prove. Ross wrote in 1899, that the anopheles seemed to prefer, as a rule, natural collections of water on outskirts of town and in rural districts as a place of deposit for eggs. If Giles is right and the anopheles is omnipresent, as assuredly the culex is, it will be plainly evident that to hope for a wholesale massacre of mosquitos or even of the larvæ would seem hardly to be entertained.

Much, however, can doubtless be done in the direction of suppressing mosquitos in a given locality. Mr. Howard lays down three lines of procedure with this object in view. First, the treatment of their breeding places with an agent destructive to the life of the larvæ; second, the abolition of breeding places by drainage; and third, the introduction of natural enemies into those breeding places which it may be impracticable or undesirable to drain or to treat with larvicides.

Before putting into practice any of these methods, it will be essential to examine, in the most careful manner possible, any district in which operations against the mosquito are to be undertaken, in order to locate accurately any pieces of water used as breeding places or which, from their appearance, seem likely to become such. In this connection, it may be well to bear in mind advice given by Ross, who says that an infallible sign in the detection of a breeding place is the invariable habit of the insects of congregating in large numbers in its near locality.

Permanent pools not used for watering stock should be treated with kerosene, swampy ground should be drained, and small pools should be filled with earth. Particular attention should be paid to this last measure, for however omnipresent the mosquito of any species may be, there can be no doubt that, as a place of deposit for its eggs, it has a decided predilection for bodies of water of circumscribed area. The reason for this is said to be that pools of comparatively small size contain no minnows, the inveterate enemy of the embryo mosquito.

Petroleum would appear to be the most effectual means of destroying the larvæ of mosquitos—judging from the results of experiments conducted up to the present. According to Mr. Howard a light fuel kerosene has been found to be most effective. The lamp-burning oil is too volatile and the crude oil is too thick. The destructive action of the oil will last from ten days to two weeks, when a similar process must be again gone through, and continued until the wished-for results have been obtained.

When a house is infested with mosquitos, it should first be screened, and after that the mosquitos within the building destroyed. In order to accomplish this latter purpose effectually many methods have been recommended. Fermi and Lumbao are in favor of the liberation of chlorine gas by treating chloride of lime with crude sulphuric acid. This plan can be carried out only in an uninhabited house, or in one in which the vapors can be allowed to remain for a considerable time. The burning of pyrethrum powder has been also suggested, while Major Havard recommends formaldehyde gas.

To effect the destruction of the larvæ in sheets of water where kerosene cannot be used, it is proposed to introduce certain kinds of fishes which are the natural enemies of the mosquito and which will devour the larvæ with avidity. Most of the small carnivorous fish which dwell in still water highly esteem the larvæ as a delicacy, and Colonel Giles declares that golden carp will consume them in enormous quantities. The common sunfish is especially partial to the eggs of the mosquito, and owing to

* Mosquitos. How They Live; How They Carry Disease; How They are Classified; How They May be Destroyed. By L. O. Howard, Ph.D. New York. McClure, Phillips & Co. 1901.

its large mouth and almost insatiable appetite, will make short work of the ovarious deposits of a vast number of the insects. The larvæ of the dragon fly have also a natural enmity to the mosquito larvæ.

Again, some authorities have asserted that certain balsamic trees of the eucalyptus and pine species possess anti-malarial properties, but Celli says that such trees so far from banishing mosquitos are favorite hiding places of the insects. By others the castor-oil shrub is said to be obnoxious in a high degree to the mosquito, while Giles claims similar properties for an Indian floating water-plant, resembling a lettuce, called in Hindustani "alkumi."

Thus it will be seen we have now at hand numerous methods of more or less efficacy for the suppression of the mosquito, and in view of the experiments to be undertaken on a large scale under the direction of Ross in Africa, and those already being conducted by our own army surgeons in Cuba, it may be anticipated that some yet more effective measures will be discovered for the ridding of the earth of these parasite-conveying pests. At any rate a crusade conducted against the eggs and larvæ would seem to promise definite and practical results.

THE SURGICAL TREATMENT OF CIRRHOSIS OF THE LIVER.

It is only very recently that it has seemed possible that anything of a radical surgical nature could be done for patients suffering from cirrhosis of the liver, but there have been already reported something over a dozen instances in which operation has been followed by improvement which may fairly be called great. As is well known the condition which surgery is called upon to relieve is the ascites, and to this end the operator seeks to establish venous communications around the obstruction in the liver, by causing adhesions to form between the great omentum and the abdominal wall, and between the liver and spleen and the diaphragm. The philosophy of this proceeding is obvious, and in practice it is found to be efficient as soon as a reasonable time has elapsed after operation. The technique of the operation is very simple and in many cases it seems possible to employ local anæsthesia, preferably in the form of infiltration. The peritoneum of the ascitic abdomen is not in a good condition for resisting infection, and it therefore appears best to avoid the use of a drain after operation so as to escape one possible source of trouble. If necessary, paracentesis may be employed in case the fluid reaccumulates before the new venous channels are in condition to relieve the congestion.

Every case of cirrhosis is, of course, not suitable for this form of treatment, since in many the condition of the kidneys makes it evident that no lasting good could be expected from any form of treatment, and in others the heart is hopelessly damaged. It is also important to remember that, in the presence of symptoms indicating serious interference with the secreting function of the liver cells, very little can be expected from surgical treatment. Those cases which exhibit ascites and its immediate consequences as the main symptoms are the ones to be selected if we wish to see what surgery can accomplish in this disease.

The resources of medicine have been taxed, and every reasonable form of internal medication has been tried, but no satisfactory treatment for cirrhosis of the liver has been found, so that if surgery can promise relief in a fair proportion of cases, and on rational grounds, the opportunity to prove the promise should not be denied. In a number of the reported cases treated by operation, the ascites seems to have been actually cured and the patients have returned to a condition of apparently normal health. When such a favorable outcome is observed, the indication of course is that the vitality of the secreting cells of the liver has not been too seriously interfered with, and as soon as the pressure has been taken off, they have resumed their normal functions. Frazier (*Annals of Surgery*, June, 1901), reports a case of great interest belonging in this class, in which the man, who had been tapped a number of times, was operated upon and after a short time was able to return to work apparently in good health. A few other observers have had similar remarkable results, so that, although it is perhaps early to draw definite conclusions, we may say that patients with cirrhosis of the liver should always be looked at with a view to possible operation, and should have the benefit of surgery unless there are some distinct contra-indications. The operation as such is simple, practically bloodless, takes little time, involves very little handling of the viscera, and, as we have mentioned, can frequently be done without general anæsthesia. We need not be discouraged if it becomes necessary to perform paracentesis one or more times during convalescence, since the newly formed adhesions require time to develop venous channels of sufficient size to be useful.

THE CRAIG COLONY FOR EPILEPTICS.

The seventh annual report of this institution has been recently published, and narrates in a pleasing manner the progress and growth of the undertaking.

The history of the inception and development of the Craig Colony is in a high degree instructive, and should act as an incentive to philanthropists to proceed on similar lines if they are desirous of benefiting morally and physically persons suffering from this class of disorder.

The Craig Colony was founded in 1894, Governor Flower signing the bill creating it on April 24th, of that year. The first mention of the colony system made in America was by Dr. Frederick Peterson, now president of the Board of Managers, in an article published in the Medical Record in 1887. The State Charities Aid Association, inspired by Dr. Peterson's article, took up the matter, and in this course it was followed by the State Board of Charities, the outcome of the movement being that a Commission was appointed by the Legislature to choose a site. A site was selected at Sonyea and after some delay a bill authorizing its purchase was introduced, passed, and signed by the Governor.

From that day to the present time there has been no looking back, the Craig Colony has advanced steadily and surely and has amply justified the confidence of its promoters in the merits of the methods of treatment practiced therein. The year just passed has witnessed the most rapid and satisfactory progress in the admission of patients the Colony has yet had; a gain of 340 having been

made during the year. The Medical Superintendent in his report makes an eloquent plea for the State to step in and legally forbid marriage between epileptics—a law which would undoubtedly be for the welfare of the epileptics themselves and of the community at large. The health of the Colony during the period covered by the report has been satisfactory. Tuberculosis was the most common and fatal disease among its inmates.

It may be truly said of Craig Colony that it has provided an object lesson on this Continent in the intelligent treatment of epilepsy, and has proved a boon, the value of which can hardly be estimated to the unfortunate sufferers from that disease.

MILD SMALLPOX.

THE success with which the spread of any infectious disease can be controlled is directly proportionate to the ease with which it can be recognized. As a result of the beneficent influence of vaccination, smallpox has become so rare that many medical graduates have never seen a case, and their failure to recognize the disease when it comes under their notice is, therefore, in some degree pardonable. This deficiency should, however, be made good, so far as possible, by demonstrations to advanced students in the special hospitals to which the isolated cases that occur are usually sent. It appears, as is pointed out by Dr. F. Montizambert in the *British Medical Journal*, that there has for some years been prevailing in the United States a mild type of smallpox that is not recognized, and has received various names, but is often mistaken for chicken-pox or rubella. The patients are not exclusively children, are generally not confined to bed or even indoors, and exhibit as a rule but little initial fever; the eruption is scanty and discrete, and there is no secondary fever. According to statistics published by the United States Marine-Hospital Service, 11,964 cases of smallpox were reported throughout the United States between December 28, 1900, and March 29, 1901, with only 157 deaths (1.31 per cent.). A serious danger resides in the very mildness of the cases, inasmuch as, the disease failing to be recognized, proper precautions are not observed and extension takes place readily.

PROFESSOR ATWATER AND THE MEDICAL TEMPERANCE ASSOCIATION.

AT the annual meeting of the American Medical Temperance Association, held at St. Paul in June, the following preamble and resolutions were adopted:

"*Whereas*, the American Medical Temperance Association, the members of which are physicians and medical teachers who have devoted years to the study of alcohol and its effects, and who are conversant with the work done by scientific men the world over to determine the effects of alcohol when given in any quantity, have noted the teaching of Professor W. O. Atwater, of Wesleyan University, upon the food and medical value of alcohol as set forth by him in the pages of the influential lay press, be it

"*Resolved*, That this Association utterly repudiates the pro-alcoholic doctrine of the said Professor W. O. Atwater as being contrary to the evidence deduced by scientific experimentation, and that his conclusions are unwarranted by the evidence resulting from his own experiments. Be it further

"*Resolved*, That this Association regards the teaching of Professor W. O. Atwater as erroneous, and a source of danger to the laity insomuch as such teaching contributes towards the increased consumption of alcoholic beverages by giving supposed reason for their safe use.

(Signed) "N. S. Davis, M.D.,
President, Chicago, Ill.
"T. D. Crothers, M.D.,
Secretary, Hartford, Conn."

We heartily sympathize with the members of this association in their efforts to combat the evils of over-indulgence in alcoholic beverages, but we are rather sceptical as to the good that can be accomplished by opposing the deductions of scientific experiments by resolutions. This is too much the manner of combat of the antivaccinationists and others of that ilk, with whom to have associated, in the minds of the public, lay or medical, the Medical Temperance Association would be a pity. The conduct and report of experiments similar to, but disproving the conclusions drawn from those of Professor Atwater would carry more conviction to the doubters and disbelievers than scores of resolutions.

News of the Week.

Inspection of Pennsylvania Quarantines.—The Maritime Exchange of Philadelphia gave an excursion July 12, down the Delaware River, for the purpose of inspecting the maritime reporting and quarantine stations, as well as the engineering work at the new breakwater. The party consisted of Supervising Surgeon-General Wyman, of the Marine-Hospital Service, the Chiefs of the Coast Survey, Light-House Board, and National Weather Bureau, the Collector of the Port of Philadelphia, the Secretary of the Maritime Exchange of New York, and others. Great satisfaction was expressed at the admirable condition of the quarantine stations at Reedy Island and the Breakwater. The emigrant barracks at the latter place are capable, when completed, of caring for two or three hundred emigrants, while ample provision will be made for cabin passengers. Particular interest was shown in the perfected apparatuses for steam and formaldehyde disinfection, and in the systematic methods of quickly and thoroughly fumigating cargoes.

Smallpox at a Fashionable Club.—During a fourth of July entertainment at Ardsley Club, N. Y., a maid, suffering from smallpox, attended ladies in the dressing-room, thus exposing a large number to infection. A physician of the locality, who was subsequently summoned, failed to diagnose the case; the patient was then taken in a railway car to New York, whence she was promptly transferred to North Brother's Island. Great consternation prevails among the club members as to the possible spread of the disease, after such an unwarranted and inexplicable exposure. The occurrence, for some reason, was kept secret for more than a week, but as soon as it was reported to Dr. Todd, Health Officer at Dobbs Ferry, he immediately instituted such preventive measures as seemed to be warranted.

The Heat.—The hot wave under which the entire eastern part of America sweltered the first of this month, has reached Europe, and the cable brings reports of intense suffering all over the Continent from Copenhagen to Geneva and from London to St. Petersburg. Around Berlin the soil is baked to a crust for a depth of a foot or more, fruit is falling unripened from the trees, and the grass and growing vegetables are being burned, shriveled up by the parching wind, as is the ripened corn in our middle West. The statistics of the New York City Health Department show that the mortality from heat was greater in the week ending July 6, than for any

corresponding period since the records have been kept. Owing to this fact, the work of the summer corps of physicians in visiting tenement houses and caring for all sick children not already under medical supervision, was begun a week earlier than usual. The number of physicians in this corps has been increased from fifty to seventy-five.

Blackmailing Druggists.—A gang of swindlers has been profiting by the fears of numerous pharmacists in Brooklyn excited by an ingenious though despisable trick. A man goes to a drug store with a simple prescription, has it made up, and takes the mixture away with him. In an hour or two or the following day the purchaser returns with the medicine which he says he gave to his wife or child, as the case may be, and that the patient was nearly killed by poison which was there through the blunder of the compounder. He says his physician has analyzed the mixture and demonstrated the presence of poison and he allows the druggist to test it then and there. The poison is of course found, as the swindler has added it himself, and he thereupon announces his determination to sue the druggist for damages to atone for the results of his alleged blunder. If the pharmacist becomes frightened at the idea of a suit for damages, and thinks it may be possible that a mistake has been made, he may accept the suggestion of the blackmailer, to settle the case out of court. The amount of settlement is said to vary from $50 to $200.

The Journal of Physical Therapeutics, an English publication, now in its second volume, has recently extended to Dr. Margaret A. Cleaves, of this city, an invitation to become its American editor. The editor-in-chief is Dr. W. S. Hedley, of London. Among the subjects to be treated of in this journal as being within the scope of "physical therapeutics" are electro-therapeutics, hydro-therapeutics, vibro-therapeutics, or treatment by vibration, photo-therapeutics, or treatment by light, radio-therapeutics, or treatment by the radiations of an x-ray tube, balneo-therapeutics, or treatment by baths, aëro-therapeutics, or treatment by compressed or rarified air; therapeutic and hygienic exercises, massage and manipulations, dietetics, climatology, and heat and cold also come within the scope of "physical therapeutics." The journal and its readers are to be congratulated upon having secured the services of an American editor of acknowledged ability and practical experience, such as Dr. Cleaves.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, for the week ending July 13, 1901: July 5. Asst. Surgeon R. T. Atkinson, ordered to the Washington Navy Yard, July 8. Asst. Surgeon A. W. Balch, ordered to the Wabash, July 8. July 6.—Asst. Surgeon J. R. Whiting, detached from the Dixie, and ordered home to wait orders. Doctors P. E. McDonnold and R. M. Young, appointed Asst. Surgeons from July 2, 1901. July 8. Asst. Surgeon M. V. Stone, ordered to Naval Hospital, Mare Island, Cal. Asst. Surgeon R. T. Orvis, detached from Naval Hospital, Mare Island, July 20, and ordered to the Pensacola. Asst. Surgeon R. R. Richardson, detached from the Naval Hospital, New York, and ordered to Naval Hospital, Newport, R. I. July 9. —Asst. Surgeon A. E. Peck, detached from the Pensacola, July 20, and ordered to the Asiatic Station as the relief of Asst. Surgeon F. L. Benton.

The Enno Sander Prize for 1901-1902. The Enno Sander Prize of the Association of Military Surgeons of the United States has for 1901-1902 been generously increased by its founder to consist of a gold medal, valued at $100, and $100 in cash. The subject for this year is "The Most Practicable Organization for the Medical Department of the United States Army in Active Service." The following are the conditions of the competition:

1. Competition is open to all persons eligible to active or associate membership in the Association of Military Surgeons of the United States. 2. The prize will be awarded upon the recommendation of a Board of Award selected by the Executive Committee. The Board will determine upon the essay to which the prize shall be awarded, and will also recommend such of the other papers submitted, as it may see fit, for honorable mention. 3. In fixing the precedence of the essays submitted, the Board will take into consideration—primarily—originality, comprehensiveness, and the practicability and utility of the opinion advanced, and—secondarily—literary character. 4. Essays will consist of not less than ten thousand, nor more than twenty thousand words, exclusive of tables. 5. Each competitor must send three typewritten copies of his essay in a sealed envelope to the Secretary of the Association, so as to reach that officer on or before February 28, 1902. 6. The essay shall contain nothing to indicate the identity of the author. Each one, however, will be authenticated by a *nom de plume*, a copy of which shall, at the same time as the essay, be transmitted to the secretary in a sealed envelope together with the author's name, rank, and address. 7. The envelope containing the name of the successful competitor will be publicly opened at the next succeeding annual meeting of the Association, and the prize thereupon awarded. 8. The successful essay becomes the property of the Association of Military Surgeons of the United States, and will appear in its publications.

The Board of Award is composed of the Hon. William Cary Sanger, Assistant Secretary of War, Brigadier-General George Miller Sternberg, Surgeon-General U. S. Army, and an officer of the line to be announced later.

Unlicensed Pharmacists in the Employment of the City.—The Municipal Civil Service Commission has decided that all applicants for the position of druggist in any of the city institutions must first pass an examination before the State Board of Pharmacy. This action was taken because of complaints that the Municipal Commission had been certifying pharmacists who held no license, and that it was a violation of the law to do so. Hitherto the board has certified pharmacists in the belief that the same law applied to them as to engineers. The law requires that engineers must have a license before they can be employed in any of the city departments, and the board thought that after pharmacists had been certified they would have to get a license in the regular way.

The Spitting Nuisance. The refined and gentlemanly police magistrates of this city seem to be little in sympathy with the law against spitting in public conveyances. At first a few misguided expectorators were fined and hope arose that the elevated and street cars might no longer be the perambulating spittoons, which they have for so many years served. But this impulse to cleanliness and hygienic decency was short-lived, and now the occasional spitter who may be arrested for specially aggravated indulgence in his filthy habit is promptly released by the magistrate with some such comment as "the companies ought to provide

spittoons," or "this is a harsh rule. I often spit myself," or "soon a man will have no liberty to do anything he wishes." The point is also insisted upon that an offender must first be warned that he is breaking the law and can be arrested only when he persists in spitting on the floor after the warning has been given, yet the notices posted in all the cars would seem to take away from one the possibility of a plea of ignorance of the law.

Examinations for Bacteriologists.—An examination for the position of Assistant Bacteriologist, Class I, salary $800, will be held by the Municipal Civil Service Commission on July 29, 1901, at 10 A. M., and an examination for the position of Assistant Bacteriologist, Class II, salary $1,200, will be held on July 31, at the same place and hour. Candidates for Class II must be able to carry on original investigations. Subjects of the examinations are: Technical knowledge, experience, mathematics, writing a report on an assumed state of facts. Applicants should address Lee Phillips, Secretary, Municipal Civil Service Commission, 346 Broadway. For particulars as to the examination, application should be made to F. G. Ireland, Chief Examiner.

Rabies prevails to an alarming extent among the cattle, sheep, and dogs in the farming district of Romulus near Ithaca in New York State. The disease was imported in a mad bull pup about a month ago. No human beings, so far as is known, have been bitten by any of the affected animals.

Orrhotherapy in Plant Diseases.—An account has been published in France of certain successful experiments in the treatment of rust in plants by impregnating the soil in which the diseased plants were growing with a culture of the causative microorganism. Mr. Beauverie is the agriculturist who made the experiments and the disease to which he rendered the plants immune was caused by the presence of botrytis cinerea.

A New Maternity Hospital.—The Manhattan Maternity Hospital and Dispensary was incorporated on July 9. The objects of the incorporators are stated to be to maintain in New York City a maternity hospital, to provide hospital accommodations for women and children, to supply medical attendance for poor women at their own homes, and to maintain a training school for nurses. The directors are Daniel S. Lamont, Cornelius Vanderbilt, Percy R. Pyne, Frank L. Polk, Moses Taylor, Harry S. Thompson, and William Thorne.

An Anti-Cigarette League was in session last week in Buffalo. There were about six hundred delegates, representing many local organizations in this country and Canada, present at the opening session. Addresses were made by President Elwood Brown and Secretary Charles Fisk, of Chicago, and a number of papers were read showing the injurious effects to the consumers and others of indulgence in cigarette smoking, and discussing the most practical measures for bringing about a diminution of the evil.

A New Bellevue Hospital.—At a meeting of the State Board of Charities, held in Albany on July 10, a resolution was adopted urging the New York City authorities to consider favorably the subject of the erection of a new and modern hospital to take the place of Bellevue as soon as possible. The board also suggested that the compensation of attendants and other employes in Bellevue Hospital should be reasonably increased, so as to [illegible] services of competent and satisfactory [illegible] ants, and that suitable provision should be made for their care in order that the services of such competent and satisfactory help may be retained. This resolution was taken because of the fact that the demands upon Bellevue Hospital are greater than upon any other hospital in this country, and of the belief that the main buildings of the hospital are too old and ill-adapted to their purposes to be sufficient to meet the proper demands of the service. The main building was erected over a century ago for an almshouse. Last year 25,000 patients were treated in the hospital.

The Plague in Egypt.—The United States consular representative at Cairo has informed the State Department that the bubonic plague, which prevails in many of the towns of Egypt, is of a virulent and destructive type, and on account of its rapid development and the exceptionally high rate of mortality, general apprehension and alarm prevail throughout the country. During the week preceding June 19 there were twenty-three cases reported, twenty-one of which were at Seagazig and two at Minieh. Sixteen cases were admitted to the hospital and five men were found dead of the disease outside of the hospital at the former place. Of those admitted to the hospital six died. The usual evidences of disease among rats were noted before the occurrence of the disease in the human inhabitants. Dr. Edington, of Cape Town, however, has taken the ground, after a series of bacteriological experiments, that there is at most a very distant relationship between bubonic plague in man and the rat plague, and that the two diseases are not intercommunicable.

Gen. Leonard Wood, who has been suffering from typhoid fever, is reported to be convalescent and happily out of danger.

A Doctor and a Nurse.—The newspapers state that one of the internes in a Brooklyn hospital is under discipline for having kissed, or rather for having been caught kissing, one of the young and comely members of the training school.

Obituary Notes.—Dr. James H. P. Wise died on July 10 at Morgan City, La. He was born in Northampton, Mass., fifty-six years ago. He served during the Civil War with the Twentieth New York Calvary, being stationed for some time in Louisiana. At the end of the war, he returned to that State and entered the now defunct New Orleans School of Medicine, from which he obtained his degree of M. D. in 1860. He first served in the U. S. Marine Hospital at New Orleans, and later entered the medical corps of the army, being with the First United States Cavalry. Moving to Morgan City in 1880, he became the local leader of the Democratic party, was ten years mayor of the town, collector of the port, quarantine officer, and president of the Board of Trade.

Dr. George H. McMurray died of diabetes at Glens Falls, N. Y., on July 12th, at the age of thirty-six years. He was a graduate of the Albany Medical College in the class of 1886. At the time of his death he was secretary of the pension examining board.

Dr. Virgil D. Thompson, aged sixty-two years, a practicing dentist of Jersey City, died on Saturday last at St. Vincent's Hospital, in this city, from the result of injuries received by being knocked down by an electric car.

Dr. John D. Weaver died at Norristown, Pa., on July 12th, at the age of forty-four years. He was a graduate of the Jefferson Medical College, in the class of 1885.

Progress of Medical Science.

Journal of the Am. Med. Association, July 13th, 1901.

Periods of Stress and Their Dental Marks.—J. G. Kiernan says that the struggle of the child for existence is most marked at certain periods and each period is characterized by certain dental phenomena. The first is the period of first dentition. Here, coincident with teething, the child is gaining its impressions of the outside world, is learning to walk and talk and is also developing its eliminative organs, especially the rectum. These varied functions constitute a strain on the system the effects of which are most often evinced through the teeth and jaws. The second period reaches from the second to the sixth year, centering about the time of eruption of the sixth year molar. With the eruption of this molar, premature puberty, sexual precocity, epilepsy, insanity, gout, rheumatism, obesity, and other nutritive degeneracies may occur. All have been charged to the eruption of the sixth year molar, whereas its irregular or difficult eruption is, like them, an expression of constitutional stress. Hygiene of the teeth at this period means also constitutional, mental and moral hygiene.

The next important period of stress is practically that of the second dentition. Here there is a foreshadowing of the mental and nervous phenomena of the following period of stress. Sexual development now frequently receives its initiative. What is true of neuropathic children earlier is true at this time of ordinary children, under conditions of stress. There are disturbed sleep, irritability, apprehension, strange ideas, great sensitiveness to external impressions, high temperature, delirium, convulsions from slight causes, disagreeably anxious, dreams, romancing, intense feeling, periodic headache, muscular twitching, capricious appetite, and marked intolerance of stimulants and narcotics. The struggle for existence between the developing alimentary and other systems, between the second and sixth year, produce effects which are most felt during the sixth to twelfth year.

The period of puberty should include the period from the appearance of the menses or the formation of spermatozoa until the completion of the twenty-fifth year. The appearance of the wisdom tooth at this time marks human maturity, which was the reason that twenty-five was selected for the age of maturity by the code of Napoleon. During this period it is possible to correct dental and maxillary irregularities with benefit to the subject. Every one of the conditions enumerated as due to strain during the period between the ages of six and twelve may reappear. In addition there occurs a type of mental disorder called hebephrenia, or insanity of puberty, which is practically incurable after its development. This is an insanity peculiarly charged to cigarette-smoking, masturbation, overstudy, religious excitement, and "love," all of which are the expressions of the defects and not their cause. The final periods of human life are those of the climacteric and the senile period. The first is accompanied by the menopause in women and prostate change in men. The dental conditions marking these two periods of stress are generally involutional in character and require prothesis or treatment and not correction.

Infectious Diseases.—A. M. Stevens, in this paper enumerates the various diseases which may be transmitted from the mouth of one patient to the mouth of another by means of dental instruments and apparatus. Syphilis, scarlet fever, diphtheria, and erysipelas are especially mentioned, and a plea is made for the more careful observance by dentists of the rules of modern antisepsis.

The Treatment of Cutaneous Cancer.—M. L. Heidingsfeld commends the use of arsenous acid, mixed with equal parts of pulverized gum-arabic, to which sufficient water is added to make a paste of the consistency of butter, and enough cocaine crystals to alleviate the anticipated painful reaction, as recommended by Marsden, Robinson, Gottheil, and Stelwagon. He has found it expedient to add ten per cent. glycerin before adding water, which prevents the paste from becoming too dry, and therefore prolongs and intensifies its action; the reactionary pain is also diminished by the glycerin.

℞ Ac. arseniosi,
Pulv. gum acaciæ, aa 5
Cocainæ nitr. cryst 2
Glycerin. 2
Aquæ q. s.
M. Ft. paste. Sig.: Apply locally.

The paste is applied directly to the ulcerated surface after being uniformly spread on a piece of muslin or linen, which has previously been carefully adapted to the affected area. It dries in the course of five to ten minutes, and remains firmly adherent until its removal, twelve, twenty-four, or thirty-six hours later, is indicated by the pain, intensity of the reaction, or the degree of the treatment required. The after-treatment consists in the application of simple, soothing, antiphlogistic remedies combined with cold compresses saturated with a solution of alum acetate. There is some reactionary inflammation, in the form of redness and swelling, which is usually limited to the ulcer and its immediate neighborhood. Arsenious acid is prompt in results, easily limited and controlled, spares the healthy issues, exerts a marked specific influence, and produces relatively little distress and subjective disturbance. It promotes prompt cicatrization, and speedily converts a freely discharging, foul-smelling ulcer, filled with soft, mushy granulations and flabby detritus, into a firm, clean-looking sore, inhibits the discharge, and materially diminishes the inflammation of the surrounding tissues.

Relation of Syphilis to Blastomycetic Dermatitis.—H. G. Anthony refers to a case he reported a year ago of blastomycetic dermatitis engrafted on syphilitic ulcers. He quotes from various authors in relation to the condition suggested by the title of the paper, and the general contention is that the theory of a syphilitic base for blastomycetic dermatitis is the true one.

Medical News, July 13, 1901.

After-Treatment of Summer Diarrhœa of Infants and Children.—William M. Taylor declares that it is difficult to lay down any fixed rule for the return to a more ample diet after subsidence of the acute symptoms of summer diarrhœa. The condition of the intestinal tract, as evidenced by the condition of the stools, must be carefully studied by the physician. The after-treatment of this affection is essentially hygienic and dietetic. Pure modified cow's milk, diluted with barley water previously dextrinized by diastase or maltine, is most satisfactory. It is almost always possible to attain proper food for the child by beginning with a percentage milk. Kumyss is also valuable, and is especially well taken during the summer months. Beef juice is easily assimilated. Children of two or three years of age may have, besides milk, beef, mutton, or chicken broth, from which the fat has been removed. Scraped rare roast beef is a valuable addition. Dry toast or zwieback is the best form of farinaceous food; liquid diastase should be given at first. Inunction of cod-liver oil is a favorable method of improving the general condition, and is well followed by a warm sponge bath. Tendency to constipation in convalescence is best corrected by the diet, water between feedings, abdominal massage, and enemata. Purgatives, as a rule, are to be avoided. Tonics are nearly always indicated, ferric iodide and the tincture of nux vomica being among the best. The untoward symptoms of dentition should be relieved. A cool morning sponge, outdoor life, and a well-ventilated sleeping room are all valuable auxiliaries to the other lines of treatment. The buttocks should be kept scrupulously clean. In the effort to get fresh air for the child, care must be taken not to cool the body suddenly, or a second attack is likely to be precipitated.

The Medicinal Treatment of Summer Diarrhœa.—Thomas S. Southworth describes the acute gastro-intestinal affections of summer among children as (a) diarrhœa from inability to digest unsuitable articles of food; (b) diarrhœa from bacterial action in tainted milk; (c) cholera infantum, probably due to milk infection. Speaking broadly, milk, including breast milk, should be stopped in all cases of summer diarrhœa in children under two years of age which begin with vomiting or high temperature. Instead may be given dextrinized barley water, rice water, egg-albumen water, mutton broth, beef juice, and plain-boiled water if there is thirst. If there is vomiting, the stomach should rest as far as possible for twelve hours. Medicinally, castor oil and calomel in divided doses are useful. The former is especially valuable when there is much mucus in the stools. But when there is nausea and vomiting, calomel may be given, gr. 1-10 to gr. 1-6 every half-hour or hour, till one grain, or possibly more, has been taken. It is a stomachic sedative and an efficient laxative. It acts as a local disinfectant in the bowel, and stimulates hepatic secretion. When pyrexia is marked, irrigation of the bowel should be performed. Persistent vomiting calls for washing of the stomach with plain boiled water, or, in cases of acidity, a solution of sodium bicarbonate. When it is advisable to check the evacuations, opium is useful, but great caution should be observed in its administration. Stimulants are often required during the acute stages. In breast-fed infants,

nursing may generally be resumed in twenty-four hours. Cow's milk diet must be determined by the indications in the individual cases.

The Hygienic Treatment of Summer Diarrhœa of Infants.—Henry C. Hazen states that the stools should be examined, and the food modified as indicated. Special care should be given to the feeding of the child as warm weather approaches. The mother's health should be looked after. If the child is bottle-fed, the milk supply should be investigated, and the mother should be shown how to sterilize and keep sterile the milk. Bottled milk is far preferable to that kept in bulk. The utmost care must be exercised in keeping the bottles, nipples, and all utensils used in the preparation of the food, clean. The nipple should fit over the neck of the bottle. After use, the nipple and bottle should be soaked in water and then boiled in a solution of bicarbonate of sodium. Food should be given at regular intervals. Frequent drinks of cool boiled water should be given. All the surroundings of the child should conform to the rules of hygiene. Absolute quiet is essential for the sick child. The little patient should be placed on a comfortable mattress, with no superfluous covering. It should be dressed in a light, white, loosely woven, woollen shirt, a loose, light robe, and diaper. Socks are not advisable. A tub bath or sponge, with good soap, should be given daily, both for cleanliness and to aid diaphoresis.

The Diseases of Nutrition in Infants.—T. M. Rotch enumerates the following as diseases characteristic of infancy, infantile atrophy, infantile scorbutus, rachitis, and osteomalacia. The etiology of this entire group is very obscure. Classified under one head, they clearly present a picture of a vice of nutrition. The prognosis of all those diseases which have a definitely determined etiology is much graver when the infant is suffering from one of these general disturbances of nutrition. These diseases are closely associated with improper food and hygiene, and their therapeutic management should demand especial study and care in the feeding during the early months and years of life. The field for purely dietetic treatment is a vast one, and will be the means of easily saving thousands of lives which are now only thrown away. As to osteomalacia, it resembles rachitis and its treatment is the same—essentially dietetic and hygienic.

New York Medical Journal, July 13, 1901.

The Home Treatment of Pulmonary Tuberculosis.—R. H. Babcock says that the main essentials of treatment under any circumstances are an abundance of good food and sojourn in the open air. To these may be added a judicious application of hydrotherapy. With persons even in moderate circumstances these requisites can be obtained at home and often much better secured there than at some of the vaunted health resorts. The main thing to insist upon is the stay in the open air. Nearly every house has a sheltered porch which can be utilized for this purpose. The porch is screened off by canvas curtains; or a rough shed or suitable tent may be erected in the yard, so that by lowering the curtains on the side toward the wind or rain, the patient may be protected. At the same time he is to be provided with wraps and blankets with which to cover himself in case he feels chilly. If he is so feeble that he is confined to his couch, an attendant should be at hand, who may cover him up, produce friction of the extremities, or supply hot bottles if necessary. For, in carrying out this open-air treatment successfully, it is absolutely necessary to protect the invalid against taking cold. Even in our severe climate it is possible, by selecting a porch or constructing a shed on the south side of the house, and by putting a small stove nearby, to keep a patient in the open air during most of our winter days. If the individual sleeps in his bedroom in the house, then this should be the largest and sunniest apartment and its windows should be kept open all day. Even at night, at least one window is to be open, and by means of a stove or fireplace and screens the patient can be kept comfortably warm.

The Influence of Mouth-Breathing upon the Dental Arch.—M. D. Lederman says that, though the alveolar process is the thickest part of the maxillary bone, it is also the most spongy portion, and one can readily appreciate the possible untoward results that faultily directed atmospheric and muscular pressure might produce. Such pressure would, no doubt, disturb the position of the advancing teeth, as comparatively slight forces may deflect the course of an eruptive tooth. The temporary teeth seldom deviate from their proper position in the alveolar arch, but irregularity of arrangement in the permanent set is not an uncommon occurrence. The most common forms of such displacement are caused by the presence of temporary teeth beyond the proper time of shedding, owing to some disturbance in the process of absorption. This condition is frequently secondary to some defect in the general system, and the evil influences of mouth-breathing due to nasal and post-nasal growths are so common in early life, that attention to the local affection is emphatically indicated. Retarded oxidation with its consequences so often exists under such circumstances that we should certainly appreciate the necessity of getting rid of the pathological factor. The obvious lesson therefore is to attend to the matter of free and unimpeded nasal respiration. If this can be brought about, the development of the dental arch will proceed along normal lines.

The Boston Medical and Surgical Journal, July 11, 1901.

Albuminuric Retinitis and Uræmic Amaurosis, with Especial Reference to Their Occurrence in Pregnancy.—Edmund D. Clap considers these troubles rare in pregnancy, but very important when they do occur. The prognosis of uræmic amaurosis as to sight is favorable for the first attack, and less and less so for each succeeding attack, but the importance of this is usually overshadowed by the uræmic condition present. The prognosis of albuminuric retinitis as to sight is favorable for the first attack, if occurring after the sixth month, but grows worse if it recurs in succeeding pregnancies. Prognosis for sight is bad before the sixth month. In retinitis albuminurica occurring early, abortion should be considered if the retinitis is of a severe type, especially if hemorrhagic, or if a slight retinitis progresses under treatment, for in these cases the life of the child is uncertain anyway, and the mother runs grave risks of eclampsia if the pregnancy goes on to term. In retinitis coming on after the sixth month, it is best to wait and watch carefully, especially in a first attack, and not to induce labor unless some other albuminuric symptom demands it.

Congenital Pelvic Malposition of Left Kidney in a Woman.—John W. Dewis reports a case in which cœliotomy was performed for supposed movable kidney. A congenitally displaced kidney was found, retroperitoneal and lying over the promontory of the sacrum, about two-thirds being in the cavity of the pelvis. The kidney cortex was exposed, and the incision again closed with catgut. Malposition does not seem to interfere with the normal function of the kidney, but it does predispose to complications—in this case to abortion. There is little to aid in diagnosis; the kidney is sensitive to touch, and there is usually marked lobulation. When there is any deformity of the pelvic organs, we should expect misplaced kidney. There is no treatment, and the foremost consideration should be the avoidance of complications.

Two Cases of Pregnancy Complicated by Mitral Insufficiency.—Henry D. Chadwick reports two cases in which the patients died, one twenty-one days and the other ten days after delivery. He holds that the only proper treatment of such cases is to watch the patient closely from the beginning, and when lack of compensation is shown by preliminary congestion, as manifested by œdema and persistent cough, it is not only justifiable, but one's duty to his patient to advise and urge upon such an unfortunate mother the necessity of saving her own life by terminating her pregnancy as speedily as possible.

Philadelphia Medical Journal, July 6 and 13, 1901

The Recognition of Early Symptoms Indicating Dangerous Forms of Insanity.—W. K. Walker quotes the following definition: "An insane person is one who is a menace to himself, to property, or to the peace and safety of others." The statement of Weir Mitchell that "the thinking general practitioner knows that what he has to deal with is not disease, but a disease plus a man," is deeply true of insanity. The study of these cases involves questions of heredity, developmental defect, predisposition or vulnerability, and incidental or exciting causes, such as toxic substances—either chemical poisons (alcohol, lead, etc.), or microbic poisons (syphilis)—and the innumerable influences of environment. In estimating the tendency to dangerous acts, attention should be directed to the emotional element in a patient, as this is so intimately associated with the defective, perverted, or diseased physical state. Ordinary life reveals many predictions of the most serious forms of insanity, as well as variations which show the transitions from the normal to the morbid state. The morbid mental state, whether of long or short duration, is marked by emotions either pleasant and agreeable or unpleasant and painful. Painful mental states are the earliest manifestations of many forms of insanity, and the invariable and characteristic accompaniment of melancholia. The depression or

dejection in this latter state excessive and out of proportion to its apparent cause. Tendency to sit and brood, apparent apathy, an attitude of dejection, and evidences of apprehension of imaginary dangers are important criteria of the depressive mental states which threaten danger and should prove sufficient warning. "Irritability" is a striking characteristic of epileptics. Epileptic insanity is marked by a tendency to acts of violence. Characteristics distinguishing epilepsy from other forms of insanity are unfounded suspicions and aversions, ideas of persecution with a tendency to fits of passion and especially to irresistible impulsions (homicide, suicide), and finally its co-existence with terrifying hallucinations. In the case of defectives, it should be remembered that they are incapable of a consecutive course of conduct and of doing anything in earnest; they are capable of showing only the less elevated sentiment and affections, and the lower instincts dominate them. They are liable to more or less sudden maniacal or melancholic attacks. Early manifestations of persecutory insanity are few. The manner is cold, harsh, and suspicious; the speech short and surly. Reticence, secretiveness, and cunning become prominent traits. The prevention of mental disease should be the aim of the physician. The patient should be placed beyond the reach of diverting and disturbing circumstances; this treatment should be early.

Dystocia from Coiling or Occlusion of the Umbilical Cord.—Edward P. Davis concludes that in seeking indication for treatment in these cases, the situation of the placenta should be ascertained as nearly as possible before labor in each pregnant woman. A study of the fetal heart sound, the placental bruit, the uterine bruit, and the beating of the mother's aorta will enable the physician to recognize a murmur in the umbilical cord. If this can be plainly heard, it is excellent evidence that the cord is coiled about the child. In the absence of a murmur, tedious labor in which no other cause for delay can be assigned, recession of the presenting part between the pains, ceasing or slowing of fetal movements, and the sensation of pain referred to the body of the uterus, afford strong presumptive evidence that the cord is coiled about the fœtus. In cases of coiling, the patient should be delivered as soon as possible and the use of forceps is justifiable. When the cord murmur is absent, but recession of the presenting part, arterial hemorrhage between the pains, pain in the uterus, uterine inertia, and delayed labor are present, a cord anatomically or practically shortened is present. Forceps is not indicated here. The patient's labor pains should be stimulated, her strength maintained, the child delivered so soon as the head is born, and the placenta removed as soon as possible. When there is a knot or occlusion of the cord by amniotic adhesions, nothing can be done to save the life of the fœtus. In the interests of the mother, the uterus should be made to expel its contents so soon as fetal death is positively diagnosed.

Coxalgia.—E. H. Coover believes that in hip-joint disease the action of cold is to allay inflammation, arrest suppuration, and promote a healthy nutrition. It shortens the stages and lessens the severity of the disease. If cases are taken in time, there will be little or no deformity, and little danger of wasting the strength of the body or of a fatal issue. It is not claimed that cold destroys the bacteria, but that it renders them inactive, thus giving to nature the chance to restore broken-down tissue. This treatment by continued application of cold, must be watched, and the condition of the patient must be carefully considered. If the effect is depressing, the direct application of the ice-cap must be discontinued, and several layers of some fabric or dry paper be interposed between it and the skin. The writer describes several interesting cases in which the continuous application of the ice-cap to the affected part resulted in either great relief or recovery.

Skin Grafting by Means of Freezing, with Reports of Some Cases. Gaston Torrance describes the method. The area from which the skin graft is to be taken is frozen with ethyl chloride, after which the skin is removed by a sterile razor, and while still frozen is applied at once to the spot to be grafted. During the process of thawing, the graft becomes "glued" to the wound, and is soon closely adherent. A portion of the corium is removed with the epidermis. The grafts are covered with green protective strips, and the part enveloped in a piece of lint covered with boracic ointment. The method is painless, and enables one to cover considerable areas at a sitting, and dispenses with the use of a general anæsthetic.

American Medicine, July 13, 1901.

Ankylostomiasis in the United States; Report of a Case.—Herman B. Allyn and M. Behrend report this case. The patient was an Italian boy fifteen years old. He complained of pain in the epigastrium and muscular weakness. Family history was negative. His color was a light tan or greenish yellow hue. The conjunctiva and sclera were blanched, the tongue very pale and covered with a heavy white fur, the teeth spotted with sordes, the mucous membrane of the mouth almost colorless. The pupils were equal and dilated, the legs slightly œdematous, the knee-jerks were absent. The vessels of the neck pulsated strongly. The percussion area of the heart was increased, the impulse increased in area and forcible, and a loud systolic murmur was audible all over the heart and in the cervical vessels. There was much mental hebetude. Examination of the feces showed numerous eggs of the ankylostoma duodenale. Scattered retinal hemorrhages were seen in each eye. The urine showed neither albumin nor sugar. After the administration of thymol the boy steadily improved. The disease occurs especially among those whose habits and occupation bring them in contact with the soil. This point and the existence of a secondary anæmia, chlorotic in type, but especially the discovery of ova of ankylostoma or the parasite itself in the stools, clinch the diagnosis. Practically all the later observers agree that thymol is the most efficient remedy. It should be given after fasting, and should be followed in about two hours by a purgative, preferably castor oil. Sandwith recommends the administration of two grams (thirty grains) of thymol in water at 8 A. M., and two grams at 10 A. M.

Impoverished Blood and Its Relation to Insanity.—J. W. Wherry believes that an impoverished condition of the blood and insanity go hand in hand. The importance of the dietary in acute cases of insanity cannot be overestimated. Nourishment and elimination are two great factors in their treatment. Tonics and aids to digestion and assimilation, with eliminants to remove toxic substances should be employed. The food should be specially selected, specially cooked, and specially served. The taste of the patient should be consulted. A physician should have the constant supervision of the dietary. There should be a wide variety. Nourishment is the one thing needful in these acute cases. The patient should be removed from home environment, and be placed in a hospital where the idea of getting well is predominant.

The Lancet, July 6, 1901.

A Contribution to the Pathogenesis of Cancer.—J. Marnoch reports certain experiments made on guinea pigs, the object of which was to show that epithelium will not grow when taken from its natural site and buried deeply in the tissues, more especially those of mesoblastic origin, or in the various cavities of the body. Incisions were made in the abdominal wall marking out a small ellipse, and thereafter the edges were raised up so as to form flaps and united by sutures over the ellipse, so that the latter came to lie in the subcutaneous tissue under a linear wound. After two weeks the animal was killed and a portion of the abdominal wall covering and including the site of the ellipse was excised and examined. The operation wound was found healed by primary union, and the skin ellipse included beneath it had disappeared; that is, the epidermis had completely gone and what remained appeared to be the corium. Other experiments along the same line gave identical results. The latter are in opposition to those of Kaufmann, who found that buried epidermis continued to live and became converted into a cyst-like tumor. Marnoch believes that when epidermis under varying conditions, is transplanted into or buried beneath a tissue of mesoblastic origin, even though it may continue to live, it does not manifest the properties of a cancerous growth. The author therefore feels bound to conclude that a cancer tumor is not merely epidermis which has found its way deeply into the underlying parts, but that the epithelium entering into the composition of these tumors, must, for some ulterior reason, be endowed with specific properties, not merely of proliferation, but of burrowing into foreign parts. What this particular property depends upon, whether it is parasitical or not, remains as yet, we may say, in great part unsettled. On the one hand, we have the allegations that in the case of the epithelium of the ovary, at any rate, all that is necessary in order to cause it to exhibit the properties of cancer epithelium is to set it free in a cavity such as the peritoneal. On the other hand, we have authors asserting quite as confidently that the disease is a parasitic one, that the parasite can be cultivated artificially, and when that it is introduced into the system of a suitable animal it occasions a tumor at least of epitheliomatous nature. In how far we are to conclude for the one view or the other, or whether the truth may reside in either, is probably in the minds of most pathologists and practical surgeons as yet of the nature of a *questio vexata*. The coincidence of the outbreak of cancerous disease with the scraping of the

ovary and transplantation of its epithelium to the peritoneum seems on the face of it a very remarkable one, and quite possibly it is an experiment which might succeed in one out of a large number of instances, but until this experiment or one allied to it has been repeated successfully most pathologists and surgeons will be inclined to hold the case *sub judice*.

Practical Points in the Treatment of Threatened Asphyxia.—R. L. Bowles devotes this lecture to stertor and the management of the apoplectic and comatose conditions Several varieties of stertor may be recognized: 1. Nasal, arising from approximation of the alæ nasi towards the septum by the in-going air, as in the act of sniffling; 2 Buccal, due to vibrations of the lips and puffings and flappings of the cheeks during inspiration or expiration. 3. Palatine, arising from vibrations of the soft palate, whether the breath passes through the mouth or the nose. 4. Pharyngeal, caused by the lolling back of the base of the tongue into near contact with the posterior wall of the pharynx. 5. Laryngeal; this variety is referable to vibrations of the chordæ vocales, as in croup and whooping cough. 6. Mucous stertor is a term which may be given to the bubbling of air through mucus or fluids in the trachea or larger air tubes.

A series of clinical histories is presented, and from a study of the cases the author draws the following conclusions: 1. That a "laryngeal stertor" may be added to the forms he formerly defined. 2. That the three forms of stertor which have a most important connection with the apoplectic state are the palatine, the pharyngeal, and the mucous stertor. 3. That these three varieties whatever their remote cause, are the immediate result of a local mechanical condition—a condition which may always and at once be changed to the great relief of the patients, and sometimes to their permanent recovery. 4. That it is necessary to keep the patient on one side, that that side should not be changed, and that the paralyzed side should be downwards. 5. That mucus and other fluids gravitate into and fill up the lower lung; and therefore that if the sides be reversed the mucus will find its way into the opposite lung. 6. That the fluid, crossing from the large bronchi of one lung to those of the opposite becomes churned into foam, and causes dangerous obstruction to the respiration. 7. That the lung, by remaining inactive and filled with mucus for a long period is not injured. 8. That these principles apply to all conditions in which blood, mucus, or fluid exists in the lungs, and also to all conditions allied to the apoplectic, whether there be mucus or not.

The Treatment of Glaucoma by the Excision of the Superior Cervical Ganglion of the Sympathetic.—A. L. Whitehead reports one successful case of this nature. The author thinks that the effects of the operation are both immediate and secondary. The immediate effects are relief of pain in the eye, contraction of the pupil when not fixed by adhesions, congestion of the eye, lacrymation, reduction of tension, and unilateral sweating of the head; the secondary effects are progressive reduction of tension, sometimes preceded by a temporary rise, gradual improvement in vision, slight ptosis, and some sinking of the eyeball into the orbit. The lacrymation, congestion, and sweating usually disappear within forty-eight hours. The good results attained in the case reported were attributed to the abolition of the control of the sympathetic over the vascular apparatus and secreting epithelium of the uveal tract, whereby the character and the amount of the intraocular fluid were materially altered.

Preliminary Note on the Direction of the Air Currents in Nasal Respiration—C. A. Parker, from experiments made by inhaling lycopodium and exhaling tobacco smoke, concludes that during quiet respiration in a normal nose, the air traverses the middle, the superior, and probably the fourth meatus, but never the inferior meatus. On this theory, it is difficult to explain how the inferior turbinates functionate in warming, etc., the inspired air. Spurs and deviations of the septum interfere with function only when they are in the way of the entrance of air into the middle meatus. Polypi and enlarged middle turbinates offer considerable hindrance. The same may be said of hypertrophies and growths springing from the nasopharynx. In expiration, however, the air seems to traverse the inferior meatus, and hence conditions encroaching on its lumen will interfere with expiration.

British Medical Journal, July 6, 1901.

An Address on Our Duty to the Consumptive Breadearner.—J. Burdon Sanderson believes that the breadearner whose health has been impaired by disease should be enabled to make the best of the strength that remains to him. For this end two things are necessary. The first is to bring within his reach havens of refuge, to which he can betake himself with the assurance that he will find an immediate welcome during the periods of temporary illness to which he is liable. The second is to furnish him with the means of relieving himself from the burden of overwork from the moment that the progress of the disease makes him incapable of sustaining it. He should be sure of prompt admission to the hospital whenever his state requires it. He must have rest, good air, good food, and a resting place away from his home. Sanatoria for the poor are a necessity. In Germany, every workman whose income is less than $500 a year is required by law to insure himself against sickness and old age. The fund thus made may be used to benefit the bread-earner directly, or his relatives who are dependent on him, during the period of his incapacity for work. The time of residence in the sanatorium shall be determined by the judgment of the Medical Superintendent. The patient can then resume, to a certain extent, according to his strength, his tasks as bread-earner. The writer gives the following as essential conditions of success: The choice of suitable sites and the erection and maintenance of suitable buildings. The selection of suitable patients and their prompt admission. The regulation under medical supervision of the time of residence of each invalid. The medical supervision of invalids after their discharge from the sanatorium.

Syphilitic Meningo-Myelitis; Erysipelas; Recovery.—E. F. Trevelyan reports the case of a woman twenty-three years old who contracted syphilis from her husband. Later, paraplegia supervened and soon became complete. There was loss of sensation in the legs, and all the reflexes were slightly exaggerated. There was incontinence of urine, and a large sacral bedsore developed. Later, an attack of facial erysipelas occurred. This was on March 24th. Two injections of antistreptococcus serum were given. On April 3d she could move her toes. Power in the legs began to return, and on July 19th her recovery seemed to be almost complete. The only exception was a slight weakness of the anal sphincter. The diagnosis of an incomplete myelitis, involving the lumbar enlargement and part of the lower dorsal cord, was based on the spastic paralysis, loss of sensation, paralysis of the sphincters, and bedsore. The presence of pains and cramps in the legs showed an involvement of the meninges. The meningo-myelitis was believed to be syphilitic, because there was not only undoubted evidence of past syphilis, but there were still evidences of active syphilis when paralysis supervened. The presence of paralysis combined with rigidity and exaggeration of the reflexes has been noted in spinal syphilis. There was absolute absence of any other effective cause. It is interesting to note that the attack of erysipelas was followed, at least in point of time, by improvement in the paralytic symptoms. It was imagined that the lesions consisted of an inflammation of the pia-arachnoid, probably of a syphilitic nature, and the disease had spread into the cord which it affected in a patchy fashion, and not uniformly.

Position of the Aortic Regurgitant Murmur.—T. Churton states that if a needle is passed through the third left intercostal space, close to the sternum and the upper margin of the fourth cartilage, it will traverse first the pulmonary conus and next the underlying aortic conus. When the aortic *bruit* is caused by regurgitating blood, the walls of the pulmonary conus are in contact; hence there is a continuous solid mass between the aortic conus and the auscultating ear; so the earliest sign of the murmur is usually obtained at or about the fourth left costal cartilage near the sternum. In children, women, and persons with a short chest the *bruit* may be a little higher; in old persons, with greatly enlarged heart, it is lower. Unless the murmur is very loud, it is not as a rule audible in the second space on the right side of the sternum.

The Staining of the Tubercle Bacillus.—Herbert W. G. Macleod describes the following rapid method: Thin slips of white crown glass are used, 76 mm. by 25 mm., and circular cover glasses (16 mm. = ⅔ line). On a slip cleared of all grease by ether and rectified spirit, three films are spread and "fixed." Two or three drops of carbolfuchsin are placed on each film by means of a pipette. The fluid is allowed to steam over the flame for five minutes, without boiling, fresh stain being dropped on as necessary. The slide is then washed and decolorized by dipping it into 25 per cent. nitric or sulphuric acid. A spot of Loeffler's methylene blue is placed on each film, the slide is gently warmed for a few seconds and then washed. The bacilli are usually stained perfectly. This method has proved rapid and effective

The Duration of Dreams.—G. B. Flux reports the case of a sailor to whom he administered nitrous oxide gas for the purpose of tooth extraction. While anesthetized the patient dreamed of a shipwreck, through which he had passed, in all its details. The dream could not have lasted more than ten seconds, while his experiences during the wreck covered a period of three and three-quarter hours.

Berliner Klinische Wochenschrift, June 24, 1901.

The Treatment of Obesity.—E. Stadelmann discusses the methods for reducing fat named after Harvey-Banting, Ebstein, Oertel, and Schweninger. The first of these consists mainly in the use of large quantities of meat and moderate amounts of carbohydrates, while fat is forbidden. The theory of the cure depends on the exclusion of all fat, but this desideratum is impossible to attain, for even lean meat contains enough fat to vitiate the results, while the method is open to the further objection that the heavy meat diet is likely to cause troublesome gastro-intestinal disturbances. Ebstein allows albuminous and fatty foods, but cuts down the carbohydrates, which measure is much better borne by the organism, but in many cases the method as described by its originator is not drastic enough, and the daily total has to be decreased to a much greater degree. Oertel, whose experience was mainly gained among the beer drinkers of Munich, cuts down the fluids, while Schweninger's cure is essentially the same, though exploited by methods non-professional. The author's views, which, illustrated by the report of a case in which a woman's weight was, in the space of a year, reduced from 310 pounds to 183 pounds without discomfort, are that every obesity cure must be a period of under-nutrition, and that the method in which this is attained is a matter of indifference. Great individualization is necessary, and the habits and desires of the patient must be largely consulted, and the relative proportions of food stuffs allowed governed accordingly. Every such treatment is a serious matter, to be carried out only under constant medical supervision, though, excepting exercise and massage, the accessory therapeutic measures have but little value; the use of thyroid extract is especially to be condemned, since it carries with it very serious risks and the same results may be reached by other means.

Vegetarian Diet.—Allen says that the older belief that an exclusively vegetarian diet is insufficient owing to its poverty in albumin is no longer tenable. He gives the results of three investigations, of which one is original, proving that vegetable proteids may entirely replace the animal albumins without interfering with metabolism. As a regular régime for the healthy, however, a purely vegetable diet is too inconvenient, owing to the large amounts that must be consumed, the quantity of undigested residue, the monotony, etc., ever to enjoy more than a limited popularity, but in many forms of disease it may advantageously be adopted. Neurasthenia and neuralgia are especially benefited, and many forms of gastric neurosis do well under it, as also membranous colitis and chronic constipation. Obesity, cardiac and kidney disease, exophthalmic goitre, and many skin affections are all favorably affected. Contraindications are anatomical disease of the stomach or intestinal tract, gastric atony, and all conditions of malnutrition; many persons also exhibit an idiosyncrasy which makes them bear the change badly, and in such cases it should not be persisted in.

Albuminous Decomposition in Pernicious Anæmia, Especially that Due to the Bothriocephalus Latus.—E. Rosenqvist urges the toxic nature of cryptogenetic pernicious anæmia and supports this view by a study of the anæmia due to the bothriocephalus latus. In this case, in which the presence of this parasite causes the changes, at certain times there is increased albuminous decomposition due to some poison secreted by the worm. This is not always demonstrable, however, for, in spite of the presence of the parasite, there may be periods of distinct nitrogen retention. A comparison of the results obtained by a study of this form of pernicious anæmia with those attending the disease when due to other causes leads to the conclusion that in regard to albuminous metabolism no difference exists between them.

Münchener Medicinische Wochenschrift, June [illegible], 1901.

Fat Embolism in a Tuberculous Lung Following Rupture of the Liver.—H. Engel reports a case of fat embolism noteworthy for its peculiar origin. The patient was a middle-aged man with well advanced pulmonary tuberculosis, who while walking slipped and to save himself from falling very forcibly rotated his body to the right. He experienced no immediate bad results and was able to walk home unassisted, but the next morning after a restless night, increasing dyspnœa and general thoracic pain impelled him to call a physician. The physical signs pointed to œdema of the lungs, but in spite of medication the patient's condition became steadily worse, with increasing cyanosis and failing heart action. Death occurred the same afternoon, without previous loss of consciousness. On autopsy the right lobe of the liver showed a fresh tear on its upper surface four inches long and microscopical preparations of the lung gave the typical picture of fat embolism. Serial sections of the liver showed the cells nearest the rupture to be nearly devoid of fat droplets, except a narrow circle around the edge of the cell; larger globules of fat were free between the cells. As the sections proceeded further from the injured area less fat was found between the cells and more in their interior, the larger part of the organ consisting wholly of cells completely filled with fat droplets. This observation makes it probable that the great compression, with the subsequent abrupt cessation of tension, which resulted from the trauma, caused the contained fat to be released from the cells and enabled it to enter the circulation, while the advanced pulmonary lesion no doubt contributed largely to the fatal ending, owing to the comparatively small amount of lung tissue that was left available for respiration.

The Treatment of Leg Ulcers.—Walbaum describes a dressing said to cure even large and obstinate ulcers in three weeks. After the usual thorough cleansing, wet dressings of aluminum acetate are applied until the secretion has been somewhat checked and has lost its odor, which usually takes two or three days. A compress, wet with spirit of camphor (the camphor wine of the G. P.), is then applied and covered with rubber protective, which, in turn, is surrounded with absorbent cotton and a bandage. In order to provide sufficient ventilation and prevent irritation, the rubber dam must not project far enough to touch the skin. The dressing is cheap, painless, and convenient, since it needs renewal only every second day, while the results are excellent.

Is There an Isolated Paralysis of the Cricothyroid?—W. Lublinski answers this in the affirmative, and says that he has observed it four times in each of which it was unilateral. In three of these cases diphtheria was the immediate or more remote cause and the lesion was accompanied by both motor and sensory disturbances. In one case, that of a public singer, the lesion was speedily complicated by a paralysis of the corresponding thyro-arytenoid, owing to the patient continuing her exacting employment. The ease with which this secondary lesion is brought in probably accounts for the rarity of reported cases of isolated cricothyroid palsy.

French Journals.

The Puncture of the Sacral Canal and the Epidural Method.—Fernand Cathelin states that the puncture of the sacral canal is extremely simple to perform in man. The patient is placed on the bed in a squatting position, which has the advantage of causing the liquid to diffuse rapidly, and of allowing the puncture to be made well towards the median line, or the patient may assume a laterally inclined position in order to stretch the inferior sacral ligament. The rules of asepsis must be observed in preparing the region for operation. The needle to be used is a special one six cm. long, with a diameter of seven-tenths of a millimeter. The operator places himself on the left of the patient and places the left index finger on the two sacral cornua, or rather on the last two posteri-external sacral tubercles which are under the skin, and which are easily felt even in obese subjects, one or two cm. above the gluteal groove; these tubercles limit the lateral and inferior part of the sacral V or U, the large inferior hiatus of the sacral canal, closed by a ligamentous membrane. Between these two bony prominences, underneath the last median tubercle of the sacral crest, the finger falls into a triangular depression, always very marked, towards the summit of which the needle is obliquely introduced and directed toward the anterior wall of the canal and the operator has a distinct sensation in perforating the ligament such as is felt in bursting the head of a drum. The finger is then raised, and after gently elevating the point of the needle it is inserted straight in a median plane—to avoid injuring the coccygeal nerves and their ganglia—to a depth of about three to five cm. There is no difficulty in the insertion. There are several advantages in this method: anatomically, the injections remain exclusively extravertebral; physiologically, the great advantage from this standpoint is that the injections act on an immense vascular surface; practically, a great advantage of sacral puncture is its simplicity and harmlessness; besides, it is absolutely painless. The writer advocates this method only for medical cases. Indications for its use are cases of severe neuralgia of

the lower extremities, sciatica, lumbago, severe pain of tabes, intercostal, neuralgia, and gastric crises. It may be tried in painful, inoperable cancers of the rectum, in hemorrhoidal fissures, in painful labor, and in painful articular affections of the lower extremities. It may be tried for the injection of most of the soluble medicinal substances administered by mouth, by rectum, or subcutaneously. The epidural injection is less complicated than the direct intra-venous method; its effect is as great, it is less dangerous, and does not cause the nodules sometimes so painful after the subcutaneous injection long time repeated.—*La Presse Médicale*, June 15, 1901.

Phototherapy. Physiopathological and Clinical Studies of the Electric Light Baths.—Ch. Colombo describes one of the first effects of this light bath to be augmentation of the number of pulsations and respirations. They are both fuller and the respirations are more profound. After the bath, besides the copious perspiration, an erythematous condition of the skin has been noted, which begins immediately after the lamps begin to burn. Loss of flesh has occurred in all the cases of obesity, especially after prolonged treatment. Very advantageous results have been obtained in certain articular affections, such as inflammatory and traumatic anchyloses. Gymnastic exercises and massage are rendered more efficacious by being combined with this treatment. Remarkable results have been obtained in all forms of the vague neuralgias from which patients with the uric diathesis suffer. In certain forms of anæmia and of neurasthenia the results have been very satisfactory. Flesh has increased as well as muscular force and strength of digestion. The writer believes that this treatment is destined to play a grand part in therapeutics. It is superior to every other therapeutic agent employed as a diaphoretic, for the great rapidity with which it provokes profuse perspiration—three to ten minutes. Its great advantage is the very stimulating action which it has on all the functions of the organism. This is not caused by the temperature, but by the chemical power of the ultra-violet rays given off by the electric lamps.—*Revue Internationale de Thérapie Physique*, May 1, 1901.

Gaseous Cysts of the Intestine; Narrowing of the Pylorus.—Jaboulay declares that this affection is very rare in man, and it consists in collections of gas in the peritoneum. Gaseous infection of the intestine and of the peritoneum is not well understood in man. The gaseous cysts of the intestine, the evolution of which is slow and torpid, appear to depend upon an attenuated microbic infection. This infection is capable of causing peritonitis and occlusion. The prognosis of this malady must be reserved and the possibility of the increase of virulency of the micro-organism must be considered. This curious affection shows itself by very severe pain on pressure over the pyloric region, by an induration at this point which is strewn with gaseous cysts, and by great distension of the stomach caused as much by the reaction of the peritoneum as by the slight tenosis of the pylorus. These symptoms are in reality the classical ones of narrowing of the pylorus, but the spontaneous suffering is less intense, while that which is provoked is more acute.—*Lyon Medical*, May 26, 1901.

Perinephritic Abscesses.—E. Verstraete states that suppurative perinephritis may be total or partial. There are two periods to be considered in the evolution of a perinephritic abscess: the initial stage, when the diagnosis is necessarily uncertain and the stage when local signs demand a judicious intervention. The initial symptom is pain, lumbar pain, which is increased by effort. The pain, however, may be subacute and allow the patient to attend to his work. There are also general symptoms which consist of a general weakness and especially of a rise of temperature. The fever may resemble that of malaria. Sometimes the general phenomena are wanting so that, for ten to fifteen days, pain is really the only symptom. The duration of this affection depends on its extent, the date of intervention and the general state of the individual. As to treatment, lumbar incision is not always sufficient, it being necessary sometimes to make secondarily a lateral abdominal incision.—*Journal des Sciences Médicales de Lille*, June 8, 1901.

Three Cases of Abscess of the Liver Treated by Transpleural Incision.—Patel states that it is now conceded that when the existence of a liver abscess is diagnosed it should be opened and drained. The abscess may be anterior or posterior. The transpleural way is rational, since it allows approach to the abscess from the convex surface of the liver; it opens a direct passage for the pus, assuring perfect drainage. As compared with costal resections, it is preferable by reason of its rapidity of execution and the absence of secondary thoracic deformities. Pneumothorax and peritonitis are easily avoidable. Only purulent pleurisy cannot be foreseen, it constitutes a grave complication, but it is perhaps common to all the other operations on parts contiguous to the pleura. This complication, and is less dangerous than peritonitis, which and which follows the opening of the abscess vex surface of the liver by the abdominal *Hebdomadaire de Médecine et de Chirurgie*, June

Vesical Tuberculosis.—A Hébert in speaking symptoms of this affection, mentions pain at the Desire to urinate is extreme and is frequent both night. The position of the patient has no influence on the frequency. Rectal touch reveals alteration of the prostate and of the seminal vesicles, characterized by knobs and sensitiveness to the touch. The treatment ought to be both general and local. The general treatment is that of general tuberculosis, and besides hygienic treatment proper to all such patients, consists especially in the use of arsenic and cresote. Local treatment has for its object the suppression or diminution of the pain of hematuria, an decrease in the frequency of urination. Various solutions are used for the different indications.—*La Revue Médicale*, June 10, 1901.

Agglutination of the Bacterium Coli by Typhoid Serum.—E. Sacquépée concludes that the agglutination of the colon bacillus by typhoid serum is a very frequent phenomenon. One can isolate from the intestine of the same typhoid patient several kinds of colon bacilli variously influenced by the same serum. The relation between the agglutination of the colon bacillus and the degree of typhoidal infection or its complications remains to be precisely determined. The agglutination of the bacillus in typhoid fever seems to betray the infection or intoxication superadded to the organism by the intestinal bacilli.—*La Presse Médicale*, June

OUR LONDON LETTER

From Our Special Correspondent

PARLIAMENT—COMMITTEE ON ARMY MEDICAL SERVICE—REPORT OF NATIONAL HOSPITAL INQUIRY—SOCIETY OF ANTI-VIVISECTIONISM—LORD GRIMTHORPE ON FEES—DRUGGISTS' INSTRUCTIONS FOR DOCTORS—DR. WALDO, CORONER—THE RECENT PERSONATION CASE

London, June 28, 1901

In the House of Commons, last night, Mr Brodrick stated, in reply to a question, that he had appointed the Committee of Experts on the Army Medical Service. It includes Mr. Tooth, of St. Bartholomew's Hospital; Mr. Makins, of St. Thomas's; Mr. Fripp, of Guy's; Sir F. Treves, of the London; Dr. Ogston, Scotland; Lieut.-Col. Keogh, Ireland; Dr. Perry, of the Senate of London University; Surgeon-General Hooper, C. S. I., President of the Medical Board of the India Office. Major James, of the R. A. M. C. is to act as Secretary and Mr. Brodrick will himself take the chair.

The report of the Committee of Inquiry into the affairs of the National Hospital for the Paralyzed and Epileptic, shows that the greatest pains have been taken to get at the truth. No less than 43 witnesses were examined, most of them experts on hospital management or those who had experience in this institution. The conclusions of the Committee are given in carefully guarded language. They amount, not only to complete approval of the Medical staff, but to a condemnation of the Board and the Secretary-Director, on every point raised during the controversy. There is to be a meeting of governors and subscribers to receive the report, but if the Board and the Secretary have any self-respect they will resign their offices in advance. A few particulars from the report may interest your readers especially those connected with hospitals. The Committee find that the Staff were justified in addressing their statement last year to the governors, and they give the results of their inquiry as to diet, nursing, supply of linen, cleanliness and other matters. On the demand of the Staff to be represented on the Board, the judgment of the Committee is that it would be to the great and permanent benefit of the hospital, and they express the belief that if this had been done the present dispute would never have arisen, and would speedily have been settled. They add that the representation demanded is the smallest consistent with what is reasonable. They enter into the objections raised by the Board and show them all to be without foundation. They even inquired into the scandalous charge that the sufferings of a patient had been prolonged in the interests of medical science. This abominable slander is shown to be baseless. I suppose those who made it have lost all sense of shame and will therefore not offer an apology. The ridiculous assertion that the presence of two members of the Staff on the Board would be "calculated to destroy the reliable and philanthropic character of the hospital," is set aside by the Committee who after considering every objection of the present Board, recommended two members of the Staff to be

added, one of the two to retire each year, but to be eligible for re-election, casual vacancies in these two seats to be filled up by the Medical Committee, which is to elect them at first. As to the Secretary-Director the Committee are clearly of opinion that such an office could never be successful unless under certain conditions which they specify, adding that unfortunately in this case none of those conditions existed. They acknowledge that Mr. Rawlings devoted energy and ability to the hospital, but they find he does not possess the exceptional qualification for the larger duties which the Board put upon him and which he on many occasions was disposed to amplify. But as he acted in the spirit of the instructions he received from the Board, on them rather than on him rests the responsibility of his attitude towards the Staff. An example of that attitude is mentioned: his returning a sealed letter for the Chairman of the Board meeting, as delivering it would be acquiescense in the effacement of his own position. The Committee recommend that the office of General Director, held in conjunction with the Secretaryship, be abolished and that either: (1) The Secretary be entrusted with ordinary secretarial duties and be also the executive officer of the Board, but be restrained from interfering with the Lady Superintendent and Medical Staff, or with persons under their control; or, (2) that a Resident Medical Superintendent be appointed to discharge the duties of Senior House Physician, as the responsible head of the hospital under the Board.

On the question of payments by out-patients, which has been a prominent point in the controversy, while recognizing that there are many weighty arguments against the plan, the Committee think that so far it has not changed the character of out-patients or resulted in any manifest ill-effects.

Other questions as to the constitution and management of the hospital, its structural defects, and the changes desirable receive attention in the Report, and it may be hoped that the governors will insist on the suggested reforms being fully carried out in order to maintain the great position which has been won for the hospital by its Medical Staff.

You are not without experience of the unscrupulous tactics of faddists as a class, but you may possibly hardly have anticipated that any section of them would have attempted to wreck Hospital Sunday. This, however, is the last trick of the anti-vivisectionists. They distributed leaflets at the doors of the churches and chapels urging intending donors to restrict their contributions to hospitals without schools and others free from experimentation. The leaflet, of course recommended the pamphlet of Stephen Coleridge mentioned in a previous letter as a "guide to the charitable."

Canons Fleming and Duckworth both protested energetically against this manœuvre and probably other preachers did the same. One of these clergymen called such fighting "striking below the belt," and the Lord Mayor denounced its "meanness." But this will have no effect on the faddists, and as for Mr. Coleridge his misstatements have often been exposed. The only result is that he seizes on each occasion the opportunity to write to the papers professed explanations which are mere repetitions of his calumnies. This is well illustrated in recent numbers of the *British Medical Journal*, the editor of which has allowed Mr. Coleridge rope enough to hang himself.

The editor having inserted an article on the cruelty of "anti-vivisectionism" Mr. Coleridge has bombarded him week after week with long and angry tirades full of misstatements. These the editor has each time patiently corrected and in doing so has convicted his correspondent of garbling quotations, of appending to an advertisement of his previous "guide" a few words from an adverse review in the *Times* to produce the effect that it was commended, and of other methods of controversy equally discreditable. But the learned advocate of the "anti"-society is only thereby stimulated to further epistolary wrath. He charges the editor, who has been so patient, with breaches of the amenities of debate, pretends that he has been insulted and declares that "to pile mountains of personal abuse on his head will neither silence him nor convince the public that he is wrong." To all this the editor replies by a final endeavor to pin him to facts and to offer him space for anything *new* if he has it to say, but not for "childish reiteration of refuted statements and empty quibbles." This will perhaps be quoted as challenging further explanations, but as nothing "new" is likely to be produced we may be glad to see the closure applied to the repetition of malignant slanders and oft-refuted misstatements.

The manner in which these faddists will trifle with truth may be seen in a side issue to this controversy. At a public meeting Lord Llangattock, who occupied the chair, declared that Mr. Coleridge had never made a misstatement. Either his Lordship was in complete ignorance of what he was talking about or was making a statement which he knew to be untrue. His motive for his anti-vivisectionism he put forward as his kindly feeling towards living creatures. He was very soon reminded that the newspapers shortly before reported a battue he had held on his estate, involving the prolonged agony of hundreds of wounded pheasants that had escaped immediate death to fall from the sheltering trees in the night as their strength gradually failed. But this is sport, while an experiment on an anæsthetised guinea-pig is "torture."

Lord Grimthorpe is once more on the war path. He never had a good word for Doctors any more than for Bishops, who are his pet aversion. His Lordship has for years been a homœopathist. On one occasion he exerted himself in favor of having a holder to the doctrine of *similia similibus* on the staff of a small hospital of which he was a governor. His present quarrel with doctors arises out of the Birmingham Institute affair, and he denounces in a letter to the *Times*, the iniquity of professional trades-unionism. Perhaps Mr. Chamberlain is responsible for misleading the aged Lord, but surely a lawyer should have satisfied himself that there was some evidence in support of the Colonial Secretary's charge. Dr. Irvine assured the Medical Council that he fully understood their objections were not founded on the low fee. Yet, now Lord Grimthorpe rushes into the *Times* to accuse the Council of trade-unionism on that very ground. Further, he takes the opportunity of denouncing consultants for expecting a fee of two guineas instead of the one guinea common thirty or forty years ago. It certainly scarcely lies in the mouth of a barrister to object to so paltry a fee for a consultation while some of his profession extort twenty to fifty times as much for a brief, and do not return the money when they fail to appear and plead the case.

We are so inundated with instructions what to prescribe from makers of pharmaceutical preparations that it looks as if druggists were to be the thinking machines of the doctors. So many pamphlets and samples have come from your side that some of us began to talk of the dispensing trade becoming Americanized. But progressive English chemists are entering the competition. One firm has this week sent a penny pamphlet to consultants giving directions for the open-air treatment of consumption at home and offering a gratuitous supply of as many copies as they will distribute to their patients.

Talk of counter-prescribing after this! Must we all go to prescribing druggists to learn our profession? The sheer impudence of the thing should open the eyes of physicians to the extent to which they have encouraged tradesmen to prey on the profession.

Dr. F. J. Waldo was on Thursday elected Coroner for the City by the Court of Common Council. He had a distinguished career at Cambridge and has held a high place among sanitarians. He was for several years Medical Officer of Health for Southwark, where he did excellent work. In 1899 he delivered the Milroy Lectures at the College of Physicians, of which I sent you some account at the time. There was keen competition for the Coronership and it speaks well for the City fathers that the three selected candidates were all medical men of mark. All three, too, were barristers as well as doctors.

The conviction of Haddock for personating two students at a preliminary examination of the Dublin Conjoint Colleges has been quashed. Only printed copies of the regulations of the Colleges were produced at the trial and they, said the Lord Chief Justice for Ireland, were rightly rejected by Mr. Justice Kenny. Proof thus failing that these regulations were in accordance with the acts the conviction was quashed. It looks as if the prosecuting solicitors must be to blame.

AN IMPROVED TROCAR.

To the Editor of the Medical Record:

Sir: In your issue of July 6th, Dr. Carl Struch, of Chicago, describes and illustrates an improved trocar. I have been using this trocar for some time and find it a most excellent instrument. It was described and pictured, much as Dr. Struch describes and pictures it, in the *Deutsche Medicinische Wochenschrift* about eight months ago. I had never seen such a trocar, but a surgical instrument maker of this city informs me that his predecessor had made them thirty years ago and that old editions of the catalogue of a German surgical-instrument maker contained cuts of the improved trocar. The improvement therefore dates quite far back and it is really astonishing that it should not long ere this have been adopted more generally.

CLINICAL NOTES AND COMMENTS.*

CASES OF TRACHEOTOMY—CASES OF INTERNAL HEMORRHAGE—OPERATING UNDER DIFFICULTIES.

By WM. W. GOLDEN, M D.,
ELKINS, W. VA.

MR. PRESIDENT AND GENTLEMEN: I hope that the following few cases taken at random from my past year's work will prove of interest to you.

Tracheotomy—It was but a few days after my return from my last session at Morgantown when I received a telegram, which read as follows: "Come to see a very sick child." The patient was sixty miles away from Elkins, and was to be reached by very inferior railway facilities, such as are known only to those of us residing in the most mountainous regions of our State, affording but one chance in twenty-four hours for a round trip, and, while it consumes the hours from 7 A. M. to 8 P. M. to make the journey, it gives one hour's time only at the point of destination. Under the circumstances the vagueness of the message meant a very elaborate equipment, from santonin to a tracheotomy tube. On arrival I found the case to be one of extreme laryngeal stenosis in a girl of four. The presence of a few patches on the tonsils and pillars left little doubt as to the nature of the obstruction in the larynx. The family took the greater part of the time at my disposal in deliberating on my suggestion of tracheotomy, and, when consent was finally obtained, there remained only ten minutes for its performance. This, however, proved sufficient. The respiratory relief and general improvement were prompt and decided. The tube was dispensed with after eight days and the wound healed up readily and without any complications. The child has since been in excellent health.

This one and similar cases that have fallen to my lot before and since make me wonder what would have been the fate of these patients if intubation, instead of tracheotomy, was resorted to, in view of the fact that the tube in the former is not infrequently expelled by coughing. Not long ago I had occasion to listen to a paper read by a bright young physician, who, after detailing his experience with two intubations, sweepingly condemned tracheotomy. And this seems to be the prevailing opinion among physicians in cities and large towns. For intubation to be generally the procedure of choice in such communities there are some good reasons; partly because should re-intubation become necessary it is only a question of a few minutes for the physician to reach his patient; partly, too, because the consent of the family is generally obtained much earlier for operation, and hence a failure to give relief on account of tracheal involvement is not so apt to occur; the ease with which the necessary instruments can be procured in those localities is also a consideration. But in country practice tracheotomy, generally speaking, is not only the most advisable, but at times becomes the only available means for the relief of laryngeal stenosis. Those who are fond of pointing to the high mortality of tracheotomy in past generations forget that surgical statistics of the pre-Listerian era are useless as a guide in the present age of clean surgery. This consideration applies with particular force to tracheotomy performed for the relief of membranous laryngitis on account of the extremely filthy condition of the field of operation, which was generally to be found in these cases as result of poulticing and salving. When performed with due regard to surgical technique and cleanliness, an unfavorable result traceable to the tracheotomy should be a very rare accident. This reminds me of a very ingenious instrument devised by Dr. F. L. Hupp, of Wheeling, and described and illustrated in the MEDICAL RECORD of July 27, 1895, for the purpose of facilitating the introduction of the cannula. I have never used it, but always wish I had it at hand when the trying moment comes for the passing of the cannula through the incised trachea.

To my mind, intubation has superseded tracheotomy to no greater extent than has, for example, the practice of asepsis that of antisepsis. The indications in each case and the surroundings are to be considered, a routine adherence to either procedure being irrational. In connection with the claim often made that tracheotomy frequently causes pneumonia to develop, I pass around the photograph of a lad of six, whom I tracheotomized when he was two years of age on account of laryngeal diphtheria, complicated by a very severe pneumonia. The decided improvement which took place in his pulmonary condition soon after the operation, impressed me with the belief that tracheotomy should not figure in the etiology of pneumonia. It is noteworthy that the same charge has been made against antitoxin. The explanation for it is doubtless to be found in the fact that anything which prolongs life in cases of severe diphtheria makes the appearance of the late and natural complications and sequelæ of this disease possible, and pneumonia is one of them.

I feel that the account of my experience in the above case is quite incomplete without a reference to antitoxin. Did I use antitoxin in this case? Unfortunately for the statistics of antitoxin I found the vial broken, when its wooden casing was opened. I must add, however, that I am still adhering to the views I expressed to you on this subject two years ago in my paper on "New Remedies." Only a few days ago I had occasion to regret that it had not been used in the case of a child in the family of a fellow-practitioner. I was called in to relieve the child from imminent death, as a result of membranous obstruction in the larynx. This tracheotomy speedily and well accomplished. My suggestion to use antitoxin was not followed and the child died fifteen hours after the operation from cardiac paralysis.

Internal Hemorrhage.—Early one morning last September I was awakened to find a case of alarming pulmonary hæmorrhage at my office door. The case was that of a young man, who had apparently been in good health up to that time, except for a cough which had been annoying him for about two months. The bleeding commenced about midnight while the patient was lying quietly in bed, and he at once left his home for my office, covering the distance of seventeen miles by fast driving. The bleeding was so profuse that I was compelled to keep the patient at my office for five hours before I dared remove him to a hotel. About noon all traces of blood disappeared from his sputum. The bleeding returned, however, the next morning with even greater profuseness, so that death from drowning through the rapid accumulation of blood in his lungs seemed inevitable for a while. He slowly rallied, however, after the cessation of the bleeding, which occurred at noon that day. The next morning another attack followed, only as alarming as the preceding one. When the patient rallied from this last attack, it became evident that his survival of one more attack, should it occur, would be almost a physiological impossibility. It is perhaps needless to mention that all the usual remedies of any hæmostatic value were freely made use of during those three days; but something more than usual

* Read before the Medical Society of the State of West Virginia, at Grafton, May 23, 1901.

was needed. I therefore decided to test the claims made in recent years for gelatin. About eight ounces of a one per cent. solution of gelatin in a decinormal salt solution was injected subcutaneously in the afternoon of that day. The hemorrhage never returned after that injection. My patient died, however, one week later from general miliary tuberculosis.

The effective and lasting hæmostasis secured in this case, apparently by the action of gelatin induced me to make it a first resort in the next case of severe internal hemorrhage. It was one of intestinal hemorrhage toward the end of the fourth week of typhoid fever. There were no evidences of bleeding after the gelatin injections were commenced. In this case the remedy was also administered by the mouth. Of course, the usual remedies were not omitted, and, in addition, two three-grain powders of suprarenal capsule were chewed up by the patient in accordance with some recent recommendations. The patient died, however, the next day from exhaustion, a result which was fully expected even before the hemorrhage took place.

In 1899 I had the pleasure of calling your attention to the hæmostatic properties claimed for gelatin. A further study of the literature on this subject, together with my own personal observation since, has convinced me that gelatin is destined to rank at the head of the list of remedies for internal hemorrhage. It certainly deserves to be singled out for further trial from the scores of new remedies thrust upon us every day. The method of using it does not differ from that employed in the ordinary subcutaneous injection of a simple salt solution, with the exception that a little more time should be taken in doing it. The soreness provoked by it in the injected area is not great and can be entirely relieved by the application of cold. In an early issue this year of the *Münchener Medicinische Wochenschrift* the statement was made by Dr. Gossner that in sterilizing gelatin solutions the temperature should not exceed 100° C., and that they should be subjected to that temperature at intervals of a day or two. From a private communication from Dr. T. B. Futcher, of the Johns Hopkins Hospital, I learn that in that institution they do subject the gelatin solutions to temperatures much higher and under pressure. He writes, in part: "Temperatures above 100° C., do not seem to injure the action of gelatin, as we found that the injections definitely increased the coagulability of the blood, as determined by the coagulometer of Wright."

Operating Under Difficulties.—On the 26th of last January, I was called to operate in a case of strangulated hernia. After traveling a distance of twelve miles (which was one-third greater than the messenger stated), I found the patient, a young man of about twenty-five, suffering from a very acutely and extensively inflamed right inguinal hernia. It had become strangulated three days before. The physician, who was summoned on the first day advised an immediate operation, after having failed to reduce the hernia by taxis. The family and friends, however, preferred to exhaust their own skill before submitting to the doctor's advice. I am not aware that any sledge hammers had been used by them to drive the hernia back, but certainly all mischief that ignorant hands could do was done. The ignorance and poverty of that family were even denser than the very dense woods that surrounded their little cabin, and as under such circumstances the capacity of a house for filth is generally in inverse proportion to its size, you will readily realize how adverse the surroundings must have been to clean surgery, if I state that the house consisted of two very small rooms, which accommodated, in addition to the one-half dozen of human souls and their legitimate belongings, the dust of two generations. By the time I was ready to commence the operation, darkness had set in. In response to my call for light, the only lamp in the house was brought in, a small affair and without a chimney. Fortunately, by the time I had the partly gangrenous intestine exposed two old lanterns were procured from a neighbor. In spite of the thick incrustations upon the chimneys of these lanterns some dull light did penetrate through them, and by it I succeeded in relieving the constriction, which was found at the internal ring, and secured the intestine to the abdominal wall with the object of forming an artificial anus, hoping to close it at some future date by a secondary operation. To attempt to do anything more at that time, and especially under those circumstances, you will agree with me would have been bad surgery. Outside of the administration of the anæsthetic, which was done by Dr. Holsberry, of Kerens, the entire work devolved upon myself. The climax of annoyance was found in the fact that I was compelled to hug the stove with my back no matter at which part of the room I placed the table used for the operation. As the day was very cold and a warm room was particularly desirable under the circumstances, the stove had to be fired heavily, and this necessitated frequent glances backwards to see if my clothes were not afire.

In ten days my patient was able to be out and came to Elkins. I found the wound entirely closed by first intention. The intestinal fistula was small and by a well-fitting pad was securely occluded. The patient's bowels acted well per vias naturales, and he gained rapidly. In two weeks from the date of the operation, he was able to do ordinary house work. By that time, however, a brother practitioner succeeded in making my patient dissatisfied with the result of the operation on the ground that the wound (meaning the intestinal fistula) should have healed up long ago, and he passed out of my observation. Two months of ill-health as a result of the sudden exposure from an over-heated room to the very cold open air, which was made necessary in order to reach a train for home, was the penalty I paid for this misplaced kindness.

FECAL IMPACTION AS A FACTOR IN THE CAUSATION OF FLOATING KIDNEY, WITH THE REPORT OF A CASE.

By FREDERIC GRIFFITH, M. D.,
NEW YORK,

SURGEON TO BELLEVUE DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

Floating kidney is a well-known surgical condition and, when uncomplicated, the symptoms are plain and the examiner is seldom misled.

A history of constipation, with more or less impaction of feces along the colon, may well be taken into consideration, however, in determining the causes which produce loosened attachments of the kidney, whether the impaction is demonstrable or not.

The following case is notable from the fact that long-continued weighing down of the colon with fecal accumulations was active in the production of the kidney condition, and when it was removed a prompt recovery took place.

V., a Frenchwoman, aged twenty-five years, married, has one child. The woman is a brunette, of medium height, spare build, and wiry frame. She came to me with a request that I produce an abortion upon her. Examining the woman I determined that she was probably in the second month of pregnancy.

Asking her the reasons for her desire to avoid a second childbirth, she stated that it was on account of the miserable condition in which her first pregnancy,

eleven months before, had left her; an instrumental delivery having been necessary. For several months past, she had been in regular attendance at a clinic, for "womb trouble," due, according to the physician in charge, to "improper treatment" when the child was born.

From straining over a washtub upon the seventh or eighth day of the puerperium, she had developed "floating kidney" upon the right side, with typical symptoms, and until the "womb trouble" phase had been presented to her, she had been under treatment for it and was wearing a padded corset, to retain the organ in its place, with but poor results.

Palpation of the right lumbar region in its upper part toward the middle line of the body, demonstrated a movable mass, which was the kidney and something else. The liver could be readily differentiated from it and it was the size of and felt most like a fetal head; pulsation, not transmitted from the aorta, was to be felt.

Believing that I had to deal with a fecal impaction at the junction of the ascending with the transverse colon, as a complication of the kidney condition, I gave the woman daily for three or four days, high, copious bowel irrigations, with olive oil internally in one-ounce doses, two or three times a day; this was followed by a continued treatment for constipation, from which she had suffered since childhood.

The result was most satisfactory, the fecal portion of the mass disappeared and the tumor resolved itself into the kidney outline during the course of a few days, though soreness and dragging pains remained for a longer time, but finally disappeared, and the woman recovered health.

When I met her upon my return from a vacation at the end of the summer, she informed me that the kidney trouble was all right, but that a short time after I had last seen her, she had been taken with bleedings (evidently following attempts at the production of abortion upon herself) which finally necessitated a curettage; though now she was "all well."

A case which has come to my notice very lately is that of a young woman who, while having a loosened right kidney, began to suffer from a stubborn colitis, which defied treatment until the performance of nephrorrhaphy; when, almost at once, the bowel symptoms disappeared. The pressure of the kidney upon the colon had evidently set up a subacute inflammation, and the result of the treatment of the kidney affection proved the intimate connection between the lower bowel and the kidney.

805 Madison Avenue.

ALCOHOL AND IRON IN ANÆMIA.

By T. B DOWDEN M.D.

HOWARD CITY, MICH.

I had a patient, a woman, aged thirty-three, whose menses were established at fifteen, who had always been anæmic. She married at twenty-seven and had had two miscarriages and came to me for relief. I tried all ordinary remedies, including all the (insoluble) iron preparations without avail, and finally put her on the following prescription:

℞ Iron filings ..... ℥j.
Good whiskey ..... ℥j.
Water, to make ..... ℥xvj.

A half pint of this was to be drunk every day. All that was required was to take the sixteen ounces every day, and the patient was at liberty to take it in one dose or spread out during the twenty-four hours. Well, she was a faithful patient. At the end of six weeks there was pinkness in her cheeks. In three months her cheeks were red. When she gave birth to her third effort she had grown strong and nursed the child from a well-developed breast—her chest before had been flat like a board. My object in writing this is, I believe, that a certain amount of alcohol can carry iron to the red blood corpuscles. With plenty of sleep, alcohol and oxygenized iron will put redness in the cheek.

REPEATED PARACENTESIS FOR ASCITES.

By WARREN PERRY, M.D.

FAIRBURY, NEB.

Mr. G., age sixty-seven, railroad engineer, twenty-eight years, had suffered from cardiac dropsy since 1893. The patient came into my hands in September, 1895. At that time the feet, legs, and abdomen were badly swollen. I put him on

℞ Tr. digitalis ..... ℥ii
Pot. acetatis ..... ʒvi
Buchu ni. fl. ..... ℥iii

℥i in water four times a day. Pulv. jalap co. ʒi every other night at bed time.

In three weeks he was back on his engine and worked till September, 1897, when I went away for a year. The tincture of digitalis had been increased gradually to twenty drops four times daily, which he was taking when I left. In the latter part of September, 1899, the patient came into my hands for the second time. Not being able to reduce the swelling by internal treatment, I decided to tap him, as his former physician, Dr. Andrews, had already done eight times, and below is the record of times tapped by me and amount of fluid removed at each tapping.

Tapped Oct	30, 1899,	gallons 5.
" Jan.	12, 1900,	" 4.
" April	13, 1900,	" 5½.
" May	20, 1900,	" 5.
" June	27, 1900,	" 4½.
" July	22, 1900,	" 4 quite over.
" Nov.	5, 1900,	" 5½.
" Dec.	19, 1900,	" 4+.
" Feb.	8, 1901,	" 5½.
" April	15, 1901,	" 4.
" May	13, 1901,	" 4. 3 qts.

He is now taking ten drops of tincture of digitalis three times a day, and one drachm of compound jalap powder three times a week. He is up town the next day after tapping, for I cannot keep him in bed over one day.

Temporal Periostitis of Auricular Origin Without Intra-osseous Suppuration.—H. Luc calls attention to a class of cases which may be confounded with intratympanic disease, but which are in reality quite distinct therefrom. The affection appears generally in the course of acute otitis, and is located in the temporal fossa. It is not accompanied by the usual painful manipulation characteristic of mastoid disease. Moreover, its location above and in front of the pinna of the ear is noteworthy. It generally begins as an indolent tumefaction, possibly extending to the eyelid, moderately tender on pressure, unilateral or bilateral. It may go on to suppuration, or may resolve. The mastoid is not tender to the touch. If suppuration occurs, the pointing of the purulent collection takes place on the upper wall of the auditory canal. Operative incision should be made in this location, and can be effected under cocaine. Pressure on the temporal region will tend to prevent free drainage. Strict antisepsis should be observed. The infection usually comes from the nasopharynx, and finds a point of least resistance in the tissues named.—*Revue Mensuelle de Laryngologie, etc.*

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-seventh Annual Meeting, Held at Boston, June 19, 20, and 21, 1901.

DR. GEORGE L. WALTON, OF BOSTON, PRESIDENT, IN THE CHAIR.

First Day—Wednesday, June 19.

President's Address.—The proceedings were opened by the PRESIDENT, who delivered the annual address. After speaking of the steady advance in all branches of neurology and the collateral sciences, he dwelt upon the gradual change in the practical duties of the neurologist as a consultant. His practice is not now limited to the mentally incapacitated, the nervously invalided, and the sufferers from chronic organic disease, but he is consulted by surgeon, general practitioner, and specialist to aid in the solution of problems of varied nature, particularly those affecting motion, sensation, and nutrition, involving other than purely nervous structures.

The "clearing house" function, increasing in all branches of medicine, is becoming the province of the neurologist. It is important for the student proposing to devote himself to this specialty to give the study of other specialties a prominent place in his training. We may be forced eventually to recognize the neuro-pathologist, the clinical investigator and consulting neurologist, and the practising neurologist, though not with well-defined restrictions. Even general practice tends towards subdivision; the general consultant is called not merely to share responsibilities and add weight to opinion, but also for his special proficiency in some branch of general medicine. There is no danger of the family practitioner being driven from the field. The very withdrawal of those with special training and peculiar aptitude leaves a demand to be met by those whose broad interests in humanity and whose disregard of personal comfort lead them to undertake the duties and accept the responsibilities of general practice.

Myeloma of the Spine with Compression of the Cord.—Dr. JOHN JENKS THOMAS, of Boston, reported the case of a man, thirty-nine years of age, who was attacked by severe pain between the shoulders which lasted four or five days. After that he improved but there was more or less pain on movement. Six weeks later he noticed a slight uncertainty in the use of the legs, with numbness in the legs and sensation of constriction about the abdomen. Eight weeks after there was slight diminution of sensation of touch and pain below the eighth rib, and very slight paresis of the legs without increase of reflexes. The spine was freely movable and it was not tender, but there was a slight kyphosis in the upper dorsal region. The symptoms increased, and four months after the onset the patient was confined to the bed with a paraplegia with increased reflexes, loss of sense of pain and temperature and diminution of tactile sense as far as the fourth rib, and sphincteric disturbances. At operation, a myeloma was found affecting and destroying the lamina and body of the fourth dorsal vertebra. The tumor was removed as far as possible. The wound healed well and the patient regained completely both strength and sensation in the legs and control of the bladder. The operation was performed six months ago, and there has been no return of the cord symptoms. The interesting features of the case, aside from the rarity of the tumor, were the relief of pressure on the cord by laminectomy, and the presence of dissociation of sensation in consequence of pressure on the cord from without.

Dr. P. C. KNAPP, of Boston, said he had seen the patient whose case had just been reported. The dissociation of sensory disturbances was very well marked. He thought at first that there was a glioma in the cord. Pressure from without had given rise to syringomyelic symptoms in several instances.

Dr. F. W. LANGDON, of Cincinnati, thought that caries of the spine occasionally produced dissociation of sensory symptoms.

Dr. J. J. PUTNAM, of Boston, spoke in favor of operation in cases of tumor of the spinal cord even if the entire tumor could not be removed. He referred to a sarcoma of the cord that had been entirely removed. The patient recovered from the operation and gradually improved. The operation was performed four years ago.

Cervical and Bulbar Tabes with Necropsy.—Drs. WILLIAM G. SPILLER and SOLIS COHEN, of Philadelphia, reported this case. Some of the most important symptoms were: Nocturnal incontinence of urine, beginning in 1872, drooping of the right upper lid, which could be overcome voluntarily; variation in the size of the pupils from time to time, paresis of the facial muscles, difficulty of mastication and deglutition, atrophy of the tongue, disturbance of sensation, especially of temperature and pain; sharp pains in the abdominal region and lower limbs, grayness of the optic nerves, and loss of the reaction of the irides to light and in accommodation. Ataxia was not present and the knee-jerks were preserved. The posterior roots in the lower cervical and upper thoracic region and portions of several cranial nerves were degenerated. A clinical history of the case was published in 1889. Death occurred in 1900. The authors discussed at some length the cervical and bulbar forms of tabes, very few cases of which, with necropsy, are found in literature.

Dr. CHARLES K. MILLS, of Philadelphia, said he had seen this patient several years ago, and was present at the autopsy. The case at the time he was familiar with it seemed to have the features of syringomyelia. He thought the observation was one of great value. He had observed several cases of high tabes, in one of which there was evidence of involvement of the upper part of the cord, and dissociated sensory phenomena. He preferred to call them "cervico-bulbar" cases.

Dr. H. M. THOMAS, of Baltimore, asked Dr. Spiller if articulatory disturbances were more frequently found in this form of tabes.

Dr. GEORGE W. JACOBY, of New York, was surprised to hear the view expressed that these cases were so infrequent. The purely clinical cases were not so unusual. He had had several cases under observation for several years, and had also seen the trigeminus involved in one case, and in another there was involvement of the trigeminus and the eighth nerve as well.

Dr. JOSEPH COLLINS, of New York, was of the same opinion as the last speaker regarding the supposed rarity of this condition. In a study of one hundred cases of tabes he had found five of high tabes. It was unusual to see both the sensory and motor neurons involved. Dr. Spiller's case was like one of bulbar paralysis.

Dr. JOSEPH SAILER, of Philadelphia, mentioned a case of high tabes that had been under his observation. It was accompanied by severe laryngeal crises. He asked if such crises were more frequent in this form of tabes.

Dr. Spiller, in closing the discussion, said that no mention had been made in the history of any articulatory disturbances. They were probably absent. He thought that cases of cervical tabes were not so infrequent as supposed. From his experience laryngeal crises are not necessarily more frequent in this than in other forms.

Tabes and Progressive Muscular Atrophy.—Dr. JOSEPH COLLINS, of New York, read the clinical and pathological report of a case of this form of disease.

Peripheral Pseudo-Tabes with Exaggerated Reflexes.—Dr. CHARLES K. MILLS, of Philadelphia, reported a case in which the sensory symptoms were those of tabes spinalis, but the knee-jerks and other reflexes, deep and

superficial, were exaggerated. Some hypertonicity was present, as were also bladder symptoms and changes in the iritic reflexes of one side. Autopsy and microscopical examination showed that the spinal roots and spinal cord were not degenerated except that there was limited degeneration of some of the cell bodies of the ventral horns. Marked degeneration was found in the most distal portions of the nerve trunk and in the small nerve bundles within the muscles examined. Some degenerative changes in the muscles were also present. A brief discussion of pseudo-tabes was given, and the fact was pointed out that the case upon which the paper was founded appeared to be unique.

Dr. F. X. DERCUM, of Philadelphia, thought that the exaggerated knee-jerk in Dr. Mills' case was an unusual feature. The question of neuro-tabes was a broad one and the disease bore a relation to neurotic atrophy.

Dr. JACOBY had seen the patient (whose case was reported by Dr. Collins) some years ago, and found that the history corresponded with that recorded by him at that time. The clinical diagnosis was at variance with the pathological findings, the ptahological diagnosis being multiple neuritis.

Dr. C. L. DANA, of New York, said that Dr. Collins' case gave a typical clinical picture of progressive muscular atrophy. He considered it a case of progressive muscular atrophy with tabes. The pathological report, however, changed the entire scheme. In such a long standing progressive atrophy, the nerves are ultimately involved. The disease was no doubt primarily in the spinal cord.

Dr. SPILLER considered Dr. Collins' case probably one of conjoint systemic disease with muscular atrophy of the spinal type. In Dr. Mills' case, the most interesting thing was the exaggeration of the knee-jerk occurring with neuritis.

Dr. KNAPP then presented a patient with tabes and progressive muscular atrophy, and also two brothers twelve and fourteen years of age, respectively, with well advanced muscular dystrophy.

Gunshot Wound of the Spine.—Dr. F. W. LANGDON, of Cincinnati, reported a case of gunshot wound producing fracture of the fifth thoracic vertebra, penetration of the spinal canal, and laceration of the dura. At the time of operation the cord was apparently intacts The symptoms following the injury were immediate paraplegia, both motor and sensory, with involvement of the sphincters. All reflexes were abolished excepting the plantar which was flexor in direction and sluggish in quality. At the autopsy on the fifth day, there was found a central clot in the gray matter at the level of the fifth dorsal segment, while the continuity of the white matter was fairly preserved.

Chronic Hemianæsthesia of over Seven Years' Duration from Destruction of the Carrefour Sensitif.—This was the report of a case by Drs. F. X. DERCUM and W. G. SPILLER, of Philadelphia. The patient was a mulatto who had been under observation at the Philadelphia Hospital with a right-sided hemianæsthesia and right homonymous hemianopsia, persisting over seven years. The symptoms had followed an apoplectic seizure, the resulting motor hemiplegia being slight. The patient finally died of a second apoplexy, the lesion involving the righ side of the brain. At the autopsy, an old cyst was found in the left hemisphere, in the *carrefour sensitif* (posterior third of the posterior limb of the internal capsule). The thalamus was apparently intact, except in so far as it was implicated by secondary degeneration. The motor fibres in the internal capsule were merely slightly implicated. The affected area was studied by serial microscopical sections.

The Separate Localization in the Cortex and Subcortex of the Cerebrum of the Representation of Movements and of Muscular and Cutaneous Sensibility.—This was the title of a paper by Dr. CHARLES K. MILLS, of Philadelphia. He held to the separate localization in the cortex and subcortex of the cerebrum of the representation of movements and of muscular and cutaneous sensibility, believing that the Rolandic and adjacent regions were sensorimotor, as had been held by Munk, Bastian, Luna, Dejerine, and others. He maintained that the cerebral motor zone included only the precentral, postcentral, and paracentral convolutions, the caudal extremities of the first, second, and third frontal convolutions, and the anterior one-fourth of the superior parietal convolution; and that a separate and extensive sensory zone existed which included the gyrus fornicatus, precuneus, and postparietal convolution, possibly also the hippocampal convolution, as held by Ferrier. He included the recent work to which he appealed under five heads: (1) Observations on sensory phenomena and especially on astereognosis in connection with cases in which operations guided by localization have been performed; (2) observations on cases in which operation and autopsy have demonstrated the presence of lesions strictly limited to the motor zone or to this zone and the region anterior to it, showing that no objective sensory phenomena were present; (3) clinical observations with autopsies and microscopical investigation showing the existence of the *carrefour sensitif* of Charcot, as in the case of Dercum and Spiller reported at this meeting; (4) the case of Spiller in which was demonstrated the extent of the motor cortex in man from the cortical degeneration present in amyotrophic lateral sclerosis, the region thus mapped out corresponding closely to the motor zone as given by von Monakoff and by the writer; and (5) observations on a case of softening of the superior parietal region in which astereognosis and ataxia were present, but no motor paralysis.

He believed that the cerebral sensory mechanism was compound and even complicated; that we have certain perceptive centres for cutaneous, muscular and other sensations comparable to the well-known visual and auditory perceptive centres; that we have associative centres, perhaps comparable with the speech concept centres, and that we have, third, a higher stereognostic centre, where takes place the final assemblage and arrangement of the stimuli which are to call forth movement by evoking the cells of the true motor or executive region, which is entirely separate even from the stereognostic centre.

Dr. DERCUM believed in a definite location for the sensory areas as separated from the motor areas Proof is still wanting, he said, that the motor area is at all sensory. He then described three cases in support of the view that a lesion in the motor region of the cortex does not produce astereognosis.

Dr. GEORGE L. WALTON of Boston said that no definite conclusions could be drawn from single cases on account of the lack of proportion between the symptoms and the apparent lesion. This was especially true of post-operative cases. In one case removal of a bit of cortex from the Rolandic area was followed by mind-blindness and word-deafness, functions of remote localization. The study of groups of cases, through still baffling, was more satisfactory. His study of such groups would indicate that loss of stereognostic sense is common in Rolandic lesions, and that loss of pain, touch, and temperature senses, as well as stereognostic sense, is likely to occur in lesions including both central and parietal convolutions. It seemed to him most probable, that in the Rolandic region centres existed for aggregation of all varieties of sensory memories registered in their simpler forms more posteriorly. These assembling centres are near the corresponding motor centres, possibly even overlying them, possibly again, they are in the posterior central gyrus.

Dr. KNAPP said that Dr. Mills had formerly stated that the sensory centre reached the fissure of Rolando, but now he had receded a half inch. The evidence as to astereognosis is as yet somewhat indefinite. Stereognosis is a cortical function, but we can not yet determine its exact centre, until we have established that the patient had a normal form of tactile sensibility in every other

respect. Dr. Mills had overlooked the developmental and anatomical conditions of the sensory tract and had laid too little stress on the cases of lesion of the Rolandic area in which sensory symptoms were present.

Dr. Langdon referred to a case of Jacksonian epilepsy in which, after an operation and removal of a very small portion of the cortex from the Rolandic area, there was produced well marked astereognosis.

Dr. Wharton Sinkler, of Philadelphia, mentioned a case in which a tumor involved the Rolandic area without causing any sensory disturbance. He thought that astereognosis was more frequently associated with disease of the thalamus than with disease of any other part of the brain.

Dr. Charles W. Burr, of Philadelphia, expressed the opinion that at the present time the motor cortex of the brain is motor only. That along the fissure of Rolando destruction will produce motor symptoms only, and posterior to that, sensory symptoms. He considered stereognosis an intellectual process and not a special sense. He might change his opinion at any time in regard to sensory localization.

Dr. James H. Lloyd, of Philadelphia, said there were some clinical grounds for supposing there is an area in the cortex for the special function of stereognosis. They tend to prove that it is in the superior parietal lobule.

Dr. Collins thought that the sensory area coincided with the motor area. He believed there was no centre for stereognosis, and that there was no single area for this intellectual act.

Dr. H. T. Patrick, of Chicago, said we should have more facts in regard to this matter before drawing conclusions.

Dr. E. D. Fisher, of New York, mentioned two cases in which there was a very large tumor in the Rolandic area with astereognosis from pressure. In the second case, the hand centre was excised, and this was followed by astereognosis.

Dr. Joseph Sailer, of Philadelphia, thought it was always necessary to study the other forms of sensation in the affected extremity, and called attention to the fact that transient astereognosis occurs occasionally in patients with cerebral hæmorrhage.

Dr. G. M. Hammond, of New York, agreed with the views expressed by Dr. Mills.

Dr. C. L. Dana, of New York, said that when he first began the study of this subject he believed that the motor centers had distinct definition. Cutaneous and muscular sensation have no such definite localization as was formerly supposed. He referred to a case of tumor in the parietal region without astereognosis. A piece of the motor cortex was cut out and produced disturbance of sensibility but no astereognosis.

Dr. Mills in closing the discussion said it was not true that he had withdrawn from or even greatly modified his original position. Some cases with autopsy had been referred to during the discussion which seemed to show that lesions in the Rolandic area might produce both motor and sensory symptoms. These cases would not bear critical investigation. He believed that a single case thoroughly studied, like that of Dercum and Spiller was of great value. All the recently studied cases in which astereognosis was a feature seemed to him to favor the views which he had presented.

Acute Multiple Neuritis. This was the title of the paper by Drs. C. W. Burr and D. J. McCarthy of Philadelphia. It comprised the study of a case of multiple neuritis (alcoholic), with incontinence of urine and fæces and death by cardiac failure. The examination of the central and peripheral nervous system revealed besides a parenchymatous degeneration of the vesical nerves, degeneration of the vesical and pelvic plexuses of nerves and of the pneumogastric and phrenic, degeneration of the muscles, selective in character, perivascular sclerosis in the spinal cord, and degeneration extra- and intramedullary of the anterior and posterior roots. Widespread chromatolysis of the ganglion cells of the central nervous system and the intervertebral sensory ganglia was also present.

Dr. Collins asked if there was any apparent anæmia in the case described. Dr. Burr replied that the blood had not been examined.

Dr. Patrick asked if it was common to have paralysis of the bladder and rectum in multiple neuritis, unless there was some complication.

Drs. Fisher and Knapp said it occurred very rarely in clear cases without complication.

Second Day—Thursday, June 20.

General Paralysis and Symmetrical Gangrene.—This was the title of a paper by Dr. Henry R. Stedman, of Boston. The case reported at length was that of a man thirty-five years of age, who, before coming under observation, had suffered from an obscure trouble largely neurasthenic with general malnutrition. He finally developed depressive delusions and hallucinations which were followed by an apathetic condition with semi-stupor. General paralysis was established by the progress of the case, memory defect increasing and convulsions becoming frequent. He died over a year later from exhaustion. While he was in a low condition physically from refusal of food the radial pulse of the right wrist suddenly stopped, and only a faint wave could be detected in the brachial artery. There was also absence of pulsation in the dorsalis pedis artery and a small black spot of necrosed tissue one-third of an inch in diameter appeared on the tip of the second toe of the right foot. This gradually disappeared. The nails of two of the other toes came off later. Two days after the cessation of the radial pulse, a bluish gangrenous spot appeared on the pulp of the index finger. This gradually spread, and in about two months all the soft tissue of the index finger and thumb were affected with dry gangrene to such an extent as to necessitate amputation. The process of gangrene was attended with much pain. The amputated portions with some healthy tissue were examined, but no evidence was found of arteritis the vessels being entirely healthy. There were no indications at any time of cardiac disease, embolism-thrombosis, arteriosclerosis, or renal disease. From the fact of its occurrence in a case of general paresis, it was possible to assume that syphilitic disease was largely involved in the causation of the gangrene. A series of crayon drawings and photographs of the case were exhibited.

Dr. Jacoby thought that in the case reported, as the symmetrical gangrene occured ten years after syphilitic infection it was the result of endarteritis. The words "after syphilis" should therefore be added to the title of the paper.

Dr. Spiller mentioned the case of a patient with symptoms of hysteria and Graves' disease. Symmetrical gangrene developed later. He had examined the tissues post-mortem. The central nervous system was normal. The ulnar nerve and the terminal arteries were diseased. He considered it very difficult to determine which was the primary process in this condition.

Dr. Dana spoke of a case of symmetrical gangrene in a man thirty years of age. The thumb, lips, and toes were affected. After five weeks there was considerable improvement, and he was nearly well in two months. As there was a rheumatic history, he was treated with salicylates. Symmetrical gangrene in some cases suggests a rheumatic toxæmia. The speaker had seen several other cases due to infection.

Dr. Knapp had seen Dr. Stedman's patient and agreed with Dr. Jacoby's view as to its syphilitic origin. He believed in infection as a cause of symmetrical gangrene.

Dr. B. Sachs, of New York, thought we should speak of Raynaud's disease not as a morbid entity, but as a

clinical group. According to his observations, these cases are due to venous and arterial disease. It was remarkable he said, in view of the presence of syphilis, that symmetrical gangrene does not occur more frequently in general paresis.

Dr. HAMMOND exhibited photographs of a patient with general paresis, showing gangrene of the sacral region and extremities as a terminal condition.

Dr. J. J. PUTNAM, of Boston, showed a patient with muscular dystrophy. There were double facial parsis extreme thinning of the chest, and conspicuous involvement of the muscles of the arms and forearms.

Tumors of the Corpus Callosum.—This was the title of a paper by Drs. J. J. PUTNAM and EDWARD R. WILLIAMS of Boston. They had observed three cases. Sections of the brain in two of these cases were exhibited. The symptoms in the first case were those of general pressure together with considerable inflammation of the optic nerve, leading to atrophy which eventually became complete. Pressure symptoms subsided after a time but later returned, causing rapid failure, bodily and mental, and causing also recrudescence of the optic neuritis, in spite of the fact that the nerve was atrophic. Only one or two other cases of this sort are on record. In the second case, the first signs of a tumor consisted in changes of temperament and failure of judgment, suggesting general paresis. Some months later, a difficulty in the use of one hand came on associated with disturbance of speech. Then pressure symptoms showed themselves, for the relief of which a trephining operation was done. Some of these symptoms were relieved, but the patient died two months later. In the third case, the whole course of the symptoms covered only a period of a few weeks, though the size of the tumor showed that it must have been present for a much longer time. Changes in temperament and awkwardness in the use of the legs and the left hand showed themselves first, but soon afterwards the patient became rapidly helpless and half unconscious. It was pointed out, especially in view of the fact that mental symptoms are so prominent and occur so early in these cases, that all the more recent and careful work with regard to the brain, both experimental and theoretical, indicates that there is no portion of that organ which can be considered exclusively psychical in function, although a small lesion of the frontal lobe will accomplish as much in this respect as a larger lesion of other parts.

Brain Tumor with Unusual Symptoms.—Dr. WHARTON SINKLER, of Philadelphia, reported four cases of brain tumor.

CASE I. The tumor was situated in the fissure of Rolando. Symptoms of melancholia and delusional insanity, existing for at least two or three years, were followed by Jacksonian convulsions at first thought to be hysterical. There was paresis of the left arm and leg, with attacks of clonic spasms in the arm. No sensory phenomena were present. The growth was localized in the right motor area, and was removed by operation. Death occurred a few hours later from hemorrhage and shock. This case emphasized the teaching of Horsley and others that an operation for brain tumor should be made in two stages when there is great vascularity.

CASE II. This was one of recurrent carcinoma a year after removal of the right breast for cancer. Within a few weeks, violent headache occurred, but there were no localizing symptoms. Two weeks later choked disc developed. There were hemianopsia, violent headache and vomiting, with but slight muscular symptoms. The tumor was then localized in the occipital lobe and so found at autopsy.

CASE III. A man, thirty-one years of age, had had attacks of severe headache with vertigo and occasional shooting pain in one arm and leg for a year. Later he began to have attacks in which there were paresis and incoordination of the left arm, with paresis of the face on the same side. There was diplopia from paralysis of the right inferior and right external [illegible]. It was difficult to reconcile [illegible] of a single growth, but it was [illegible] was a growth in the right [illegible]. The paresis suddenly after a convulsive seizure. A tumor [illegible] was found in the upper part of the temporosphenoidal lobe. Another similar growth was at the [illegible] upon the central surface of the pons and left crus.

CASE IV. A man of fifty, who gave no history of syphilis and had apparently been in good health until two months before coming under observation, then became hypochondriacal, morose, and indifferent to business. Soon after he showed signs of dementia, and then became semiconscious, sleeping most of the time and being difficult to arouse. He had no vomiting, complained of no pain, and there was no paralysis of motion or sensation. The deep and cutaneous reflexes were exaggerated. Optic neuritis was present. He died comatose in about ten days. A tumor was found in the right frontal lobe, involving the roof of the right lateral ventricle and the entire corpus callosum, and extending into the left frontal lobe. There was also a small growth in the left occipital lobe.

Tumor of the Brain; Operation; Recovery.—This was the report of a case by Drs. William M. Leszynsky, of New York, and James H. Glass, of Utica. The patient was a man fifty-six years of age, who had for several years complained of localized spasm, affecting the left upper and lower extremities. These attacks were followed by transient paresis of the affected parts. Ultimately the paresis became progressive and permanent. The diagnosis of a neoplasm was made, its location established, and an early operation advised. An endothelioma was found in the Rolandic area and removed. The patient made a good recovery from the effects of the operation which was performed by Dr. Glass two years ago. He is now following his daily occupation as an accountant, the present condition of partial hemiplegia being the result of the destruction of brain tissue previous to the removal of the growth. A noteworthy feature in the case was the entire absence of headache and vomiting during the course of the disease.

These three papers were discussed together.

Dr. SACHS spoke of the surprising adaptability of the brain to pressure by tumors, and the variability of the mental symptoms. He then referred to an unusual case of brain tumor that ran a course of several years. Complete dementia gradually developed. Later, all the mental symptoms disappeared. The exact location of the tumor seemed to be a matter of doubt. The growth probably originated in the optic chiasm. There was no optic neuritis, but optic atrophy developed, and complete blindness ensued. He thought it would be interesting in all cases of brain tumor, to study the visual fields. In one case, after trephining the parietal region, and attempting the removal of a tumor, the trigeminal pain which had previously existed entirely disappeared.

Dr. KNAPP mentioned two cases of tumor of the corpus callosum. In one case, the patient died with symptoms of meningitis. In the other case, which also proved fatal, there was no real paralysis at first, but, later, severe headache, vomiting, unconsciousness and left hemiplegia developed.

Dr. LLOYD spoke of the symptomatology of tumors, and referred to a case of tumor of the callosum giving rise to a curious symptom which he called "lock spasm." The other symptoms were unilateral. When attempts were made to grasp an object, the tonic spasm in the muscles of the hand became so marked that the patient was unable to relax his grasp for some time. This symptom showed evidence of cortical irritation and might prove to be of value in diagnosis.

Dr. THEODORE DILLER, of Pittsburg, considered the question of doing these operations for brain tumor in two stages, in order to avoid excessive hemorrhage. He

thought that trephining for the relief of headache was justifiable in some cases.

Dr. SPILLER said that, at operation, tumors growing from the dura were likely to be accompanied by severe hemorrhage. He had noticed that these tumors produced considerable pressure without occasioning severe symptoms. He questioned the advisability of operating on tumors of the cerebellum.

Dr. WILLIAM BROWNING, of Brooklyn, deemed trephining unjustifiable for the relief of headache, as the symptoms returned. He preferred the use of depressant drugs, such as gelseminum, veratrum viride, etc.

Dr. MILLS called attention to the fact that no case of tumor of the callosum has been reported in which the tumor did not involve neighboring parts. It is probable, he thought, that tumors of the callosum give symptoms of a mental character, and also give rise to a peculiar form of ataxia. The method of operation for brain tumor should be changed. There should be no clinic, no lecture, no consultation; the strictest attention should be given to the particular case, and the operation should be finished as soon as possible.

Dr. JACOBY spoke in support of the remarks of the last speaker. He always expected a large amount of hemorrhage in operation for the removal of dural tumors.

Dr. LANGDON knew of four cases of operation for cerebellar tumor in which recovery from the operation had occurred. Three of these operations were done by Horsley and Macewen, and one case occurred in his own practice.

Dr. HAMMOND presented a plaster cast of a tumor originating in the dura and making pressure on the pons and cerebellum. The only symptoms of brain tumor were optic neuritis and vomiting.

Dr. KNAPP exhibited a specimen of tumor involving the corpus striatum.

Cerebellar Tumor.—This was the report of a case by Dr. JOSEPH SAILER, of Philadelphia. Shortly after a severe fall, the patient developed strabismus, vomiting, and a staggering gait. Later, a protrusion appeared below the external occipital protuberance, which pulsated and had a thrill and murmur, and there was an opening in the occipital bone. Vision rapidly deteriorated, and two operations were performed with the hope of evacuating a cyst, or removing a tumor, but they were without result. The child died, and multiple tyromata were found in the vermiform process. The knee-jerks had been lost until shortly before death, when they reappeared. No degeneration was found in the spinal cord.

Tumor of the Cerebellum Associated with Corpora Quadrigeminal Symptoms.—Dr. H. C. Gordinier, of Troy, reported this case, which occurred in a person twenty-one years of age. The illness began with severe frontal headache, gradual loss of vision in both eyes, and projectile vomiting. Soon after, staggering gait, with a tendency to fall to the left side, was noted, and, later, vertigo, feeling of pressure in the head, and intense occipital headache. There were double optic neuritis passing on to atrophy, slow cerebration, gradual loss of memory, choreiform movements, tremor and nystagmus. The focal symptoms were ophthalmoplegia interna, with double incomplete ophthalmoplegia externa, a marked cerebellar gait, coarse intention tremor of the hands, and ataxia of the left leg. Death occurred at the end of one year. The autopsy revealed a neuroglioma originating in the superior worm of the cerebellum, extending into the posterior quadrigeminal bodies, and involving each oculomotor nucleus. The superior cerebellar peduncles were also affected.

Dr. KNAPP thought that, in spite of the hopelessness of the condition and the danger in operating, it was worth while to operate in cases of cerebellar tumor. Out of eighteen cases, of which he had the notes, there were only two in which the knee-jerks were lost, and these were complicated with cord trouble. In all of the others the knee-jerk was exaggerated.

Dr. DERCUM said that the knee-jerk in cerebellar growths is very variable. He had seen it reappear after a prolonged absence.

Dr. BROWNING said that there is one symptom that occasionally occurs to which no reference had been made. That is the intermittent tonic contraction of the muscles of the neck, as originally described by Hughlings Jackson. He had seen this condition marked in one case that had been under his observation.

Dr. FISHER inquired as to the location of the pain in the cases just reported. In one case of which he had knowledge, the general symptoms of tumor were very plain. The pain was intense, and always located in the forehead. This was the only point indicating the possible position of the growth. At operation, nothing was found. A cerebellar tumor was revealed post-mortem.

Dr. Gordinier replied that the pain at the outset was in the frontal region, but later it became entirely and intensely occipital.

Dr. Langdon said that, in the case he had reported previously, the headache was entirely frontal for many weeks, and yet the other symptoms were distinctly cerebellar.

Dr. Sailer said that in a number of cases there was unilateral loss of the reflexes. In his case, the child denied that there was any pain in the head. The knee-jerks did not return immediately after the operation, but about two months later.

The Prognosis of Traumatic Hysteria.—Dr. PEARCE BAILEY, of New York, read a paper with this title, which was based upon the subsequent histories of seven litigated cases. From these cases he concluded that the prognosis of litigated traumatic hysteria is uncertain. Restoration of health is impossible until legal questions are ended. Heredity is often difficult to demonstrate in these cases. The younger the patient the better the prognosis. The previous condition of health is an important factor to be considered. Recovery from hysteria is especially difficult in old persons and in those suffering from chronic diseases. The mental state is the cause of hysterical symptoms, and consequently the determination of the mental condition, together with changes in character, etc., is more important from the point of view of prognosis, than is an enumeration of the purely physical symptoms. The chances of recovery from traumatic hysteria in a previously healthy person, not over thirty-five or forty years of age, are generally very good, but a cure is not absolutely certain. Recovery in these cases means ability to return to work or to resume the same kind of life as was led before the accident. It is probable that, even after such recovery, certain subjective symptoms remain for some time.

Dr. LANGDON reported a case of traumatic hysteria in a man sixty-three years of age. He had been shocked by a fall ten or twelve years before coming under observation. He went about his work after the fall, and there was no question of litigation. He was subject to attacks of astasia-abasia, and there was distinct hemianæsthesia, of which the patient was unconscious.

Dr. S. G. WEBBER, of Boston, thought it would be obtaining information of great value if we could follow up every litigation case and ascertain in how many recovery took place and in how many it did not. He had seen a patient with traumatic hysteria persisting four and a half years after the settlement of the damages. In another case with hemianæsthesia, the symptoms were still present three years after the settlement. He also spoke of a man who was in a bad condition three years after the injury. In this case there was no question of damages. Seven years later, the man still showed signs of hysteria.

Dr. KNAPP thought that, in coming to any conclusion about these cases, one could not depend on hearsay evidence. The evidence that somebody saw the patient going across the street or doing a certain amount of work,

is absolutely worthless unless the physician himself has examined that patient, in order to determine definitely what the symptoms are. Unless it can be proved that there is no longer any hemianæsthesia or any contraction of the visual fields, the patient cannot be pronounced free from the danger of recurrence of hysterical symptoms. The shifting character of the anæsthesia is sometimes pronounced. In a recent case that had been under observation for six years, this condition was present, and the patient ultimately developed all of the signs of disseminated sclerosis. In the speaker's experience, it was only in a comparatively small percentage of cases that he had been able to find complete and persistent disappearance of all the symptoms.

Dr. RIGGS had seen a patient sixty years of age who had been hurt in a street-car accident. The peculiar feature in the case was the mental condition which bore a very close resemblance to dementia. He agreed with those who held that these cases should be considered along the line of surgical injuries.

A Medico-legal Case.—Dr. JAMES HENDRIE LLOYD of Philadelphia, reported a case in which there was extensor paralysis of the forearms, in a patient who had been exposed to poisoning by hydrofluoric acid, which exactly resembled that which is caused by lead. The object of the paper was to establish the presumption that the paralysis was in reality a case of lead palsy, in spite of the fact that there was nothing positive in the history of the patient to prove that he had been exposed to lead except the very indefinite history of his having worked in a glass factory and also in a brush factory, in both of which lead is used. The medico-legal interest of the case centered upon the fact that the patient claimed that the palsy was due to exposure to hydrofluoric acid. This acid is used by etchers on glass, and is a highly corrosive poison. It acts directly upon the skin, like other corrosive poisons, such as nitric and sulphuric acids. The man's work was that of an unskilled laborer employed to rinse the glasses after they had been etched. This rinsing was done in a trough of running water, in which the amount of hydrofluoric acid must have been exceedingly small. The question arose whether under such circumstances hydrofluoric acid could act as a poison and if so, whether it could act by being absorbed without injuring the skin, and could thus cause extensor paralysis of the forearms identically like that which is seen in lead palsy.

Dr. COURTNEY said that, in the chemical process of etching, the hydrofluoric acid liberates lead.

Dr. KNAPP thought that it was important in the diagnosis to determine the presence or absence of lead in the urine. While it was the ordinary rule in lead paralysis that the extensor muscles of the forearms were affected, it was not an invariable rule. He had seen the paralysis attack the legs rather than the feet, and the shoulder muscles rather than the wrist.

Dr. Lloyd said that, under the circumstances in which the acid is used, the man simply had his arms immersed in water, which was flowing all the time, and the lead which would be liberated on the glass, would be so rapidly diluted and carried off that it would be unlikely to be absorbed. Hydrofluoric acid acts as a corrosive poison. Have we a right to suppose it can act by being absorbed through the skin, not injuring the skin, and yet with the result of producing lead poisoning?

A Clinical Classification of Insanity.—Dr. F. X. DERCUM, of Philadelphia, insisted upon the importance of the clinical study of insanity, and believed that it offered at present the only intelligible scheme of interpretation. He insisted further upon the necessity of approaching the subject from the standpoint of practical medicine, beginning with the consideration of delirium as it was met with in ordinary practice. He took up in succession the various elemental forms of insanity. These he grouped as follows: 1. Delirium, confusion, stupor. 2. Melancholia, mania, circular insanity. 3. Paranoia. 4. Neurasthenic conditions.

The considerations presented justified the following conclusions: 1. All of the mental disturbances which result from the infections, the toxæmias, the auto-intoxications, the visceral diseases, the diseases of the [illegible], pregnancy, the puerperium, and lactation, belong to the symptom-group of delirium—a delirium, confusion, stupor. Delirium, confusion and stupor are largely interchangeable terms possessing a certain degree of equivalence, and it must depend largely upon the activity of the morbid process, as well as upon its character as to which of these forms is present in a given case. 2. The melancholia-mania syndrome bears no relation to the foregoing infections, intoxications or visceral diseases. Neither mania nor melancholia ever results from them. They are diseases primarily of the nervous system—functional, so to speak—and are largely hereditary. 3. The delirium-confusion-stupor syndrome may occur at any age. It usually exists independently, but its forms may occur as complications or episodes in any of the other affections. Melancholia-mania and paranoia are related to definite periods of life.

Dr. LLOYD said it was very evident that there was great dissatisfaction with the present system of classifying insanity. With our present dearth of knowledge of the true insanities, it would be, perhaps, premature to place mania and melancholia in the same group of insanities. Clinically the two diseases are very distinct. All have seen instances in which mania and melancholia alternate in which one patient will at one time have maniacal symptoms and at another depressive symptoms.

Dr. KNAPP said he was glad that Dr. Dercum was approaching the same position that he (Knapp) had advocated, two years ago, before this Society. He only many of the cases spoken of as either melancholia or mania might much more properly be placed under the type of confusion, and others would be brought into closer relation with either neurasthenic conditions in some of the cases of mental depression, or true paranoiac conditions. In the main he agreed with the views expressed by the reader of the paper.

Dr. MILLS was not prepared to accept the idea that melancholia and mania must be included under the same clinical group, nevertheless he regarded the classification as a useful one, especially for students.

Dr. FISHER thought that a classification of insanity on a clinical basis would lead to infinite confusion.

Dr. Dercum, in closing the discussion, said he believed that the clinical classification is the clearest possible classification. As to including mania and melancholia in the same group, when we have these in the same person he did not see how we can escape from the clinical evidence that they are expressions of one and the same disease.

Third Day.—Friday, June 21.

Dispensary Treatment of Mental Diseases.—This was the title of a paper by Dr. WALTER CHANNING, of Boston. He recommended several ways of solving the problems of the increase of insanity and how it can best be prevented. These were: 1. Through discussions in medical and lay societies. 2. By instruction by means of didactic and clinical lectures to students. 3. By the investigation and treatment of patients with more or less mental disturbance while living in the general community. To accomplish the third object, a department of mental disease was established at the Boston Dispensary in 1897. Many cases of insanity have been sent to it by the physicians of all the public institutions of Boston. Also cases of neurasthenia, simple depression and alcoholism, defective children, etc. The study of defective children has gradually become an important branch of the work. Their number in the city is considerable. Many go unrecognized, and later develop into imbeciles, tramps and trouble-

nals. The women often become the mothers of illegitimate children. The work of the Mental Department at the Dispensary has shown that there are more unsuspected cases of insanity in the general community than had been supposed. Much time has been spent in the examination of each patient, which in the clinics of the other departments is less possible.

Fear of Insomnia.—Dr. Edward Cowles, of Waverly, reported the case of a patient in whom this "phobia" had existed for years, and had impelled him to resort to devices for seclusion at night and for promoting sleep. The nature of obsessions was explained to him, the imperative idea was precisely pointed out, and a proper substitute was suggested, which resulted in immediate correction of the disordered association-process and recovery. The speaker believed that such primary disorders of physiological mental processes were very common in normal subjects, and were not necessarily manifestations of constitutional neuropathic instability. The subjects of acquired or hereditary neurasthenia were only more susceptible to influences causing such "dissociations." Insistent and imperative ideas in various forms, more frequent and striking, but only further modifications or exaggerations in the workings of fundamental elements, were common to all minds. These affections should not be conceived and classified as essentially neuropathic.

These two papers were discussed together.

Dr. Diller referred to the case of a man bed-ridden with arthritis deformans, who was a subject of all sorts of obsessions. The counterpane had to be arranged in an exact position, and, at certain times of the day, he would pull out a bit of the wool from a certain portion of it. He read a certain number of hours a certain number of columns, and did everthing in an exact way. The obsessions disappeared under moral management in a few weeks.

Dr. J. W. Putnam thought that these patients have certain current mental action which is founded upon error, and yet it proceeds logically from incorrect premises. If we give them the correct premises, with the same force of logic, they improve.

Dr. Sachs entirely agreed with Dr. Channing that there is great need of more careful observation of mental cases. He could, however, see no reason whatever for divorcing the mental clinic from the general neurological clinic. In New York it is the custom for physicians to direct patients suffering from mental derangement to the neurological clinic, and if the cases are not as carefully observed as they should be, it is the fault of those in charge of the clinic, or due to lack of time. There is danger in creating further subdivision in general medical subjects. We should strive to keep these two departments in close touch with one another. He felt that it would be unwise for all of us to imitate Dr. Channing's example, except in so far as we should pay greater attention to the mental cases that come before us. As to Dr. Cowles' case he could not see that special fear of insomnia is anything else but what we, in old-fashioned term, used to call a hypochondriacal delusion. It seemed to him that some distinction should be made between such a fear as that, and the ordinary obsessions, imperative ideas, etc.

Dr. Knapp believed that it is very much better that the two departments should be closely associated instead of being separated. He thought there was an unfortunate tendency to regard neurasthenia as a manifestation of a profoundly neurotic condition, as primarily a psychical disturbance. It is primarily a fatigue neurosis. The morbid fears developing in neurasthenia should not always be regarded as a manifestation of any profound neurotic taint or degeneracy.

Dr. J. J. Putnam said that neurologists are under distinct obligation to give more attention to mental disorders than they have hitherto done. The subjects of neurology and psychiatry are gradually drawing together. In Boston, the mental clinic had worked satisfactorily. The conditions referred to by Dr. Cowles were like those which develop in cases of fatigue. We should begin by attacking the psychical defect and the building of fasle conceptions which have gradually arisen, often on very slender bases. He felt quite sure that such a method was far more possible than is ordinarily realized.

Dr. Patrick did not believe that imperative conceptions, phobias, and the like were simply manifestations of neurasthenia. He was inclined to think that they approach a pure psychosis and were not manifestations of a fatigue neurosis at all.

Dr. Dana said that the fear of insomnia as described by Dr. Cowles was not exactly of the nature of a fixed idea but came rather in the class of cases of hypochondriasis with this distinct depressing idea dominant. The various types of morbid fears, doubting manias, etc., are more or less closely related. They should not be called neurasthenic insanity. Such manifestations are evidences of degeneration and should be placed under the head of degenerative psychoses. He was in sympathy with Dr. Channing's proposition as to the establishment of a separate mental clinic. He thought that the idea of paying special attention to the mental cases is an excellent one, if for no other reason than that we may in time get the attention of the public and of our millionaires directed to provide more for this class of cases. In New York little provision is made for them, and the situation at present is a very discouraging one.

Dr. Guy Hinsdale, of Philadelphia, said that a Dispensary for Mental Diseases had been in operation in Philadelphia for the last five years. There was no difficulty whatever in the conduct of it. It was a great convenience to the members of the neurological clinics.

Dr. H. M. Thomas felt that a practical division of the neurological from the mental clinic was a very difficult one to make. In connection with the neurological clinic in Baltimore, there were men who had had special training in the examination of such cases.

Dr. Cowles, in closing the discussion, said we must go much deeper than to classify upon the superficial feature of conduct or of concrete facts from which arises this concept of harm to self. To speak of these fears as hypochondria is descriptive, but not satisfactory, as an explanation of the disease.

Dr. Channing said in conclusion that there is no essential reason why a mental department should not be connected with a neurological department. The fact is that the young neurologist is not competent to make a proper examination in a case of mental disease. In establishing a clinic of this sort, we are not separating neurology from psychiatry, but rather in this way we shall eventually bring the two together.

Record of Footprints for Studying the Gait.—Dr. Joseph Sailer, of Philadelphia, exhibited some foot-prints made by a new method which consists of smearing the soles of the feet with a mixture of oil and lamp-black, and then having the patient walk on long strips of Manila paper.

Studies with the Ergograph.—Dr. August Hoch, of Waverly, presented an ergographic method for the finer differentiation of various forms of dimmished mental or motor activity. It was found that practice shows itself normally by a rise in pull number while the average pull height remains the same. In a person with mental depression in whom no psycho-motor retardation was noticeable, but only a feeling of inadequacy, this rise in pull number was not present while the average pull height rose. The speaker claimed, therefore, that this was a method for demonstrating psycho-motor retardation even when this may be very slight.

Hysterical Paralysis Associated with Black Chromidrosis.—Dr. J. W. Putnam, of Buffalo reported the case of a patient, nineteen years of age, who was in good health until one year ago when she was affected with black chromidrosis for several months. The cheeks

and eyelids were involved. Later a hysterical paralysis of both legs occurred which lasted one week. After several months of treatment he recovered from the chromidrosis.

Dr. DANA asked what sort of stuff she painted her face with.

Dr. Putnam replied that he had expected that question. It was not an artificially produced chromidrosis, as it would become dark in his presence as one sees a person become covered with perspiration, and no person could so apply the substance as to have it cover and surround the individual eyelashes. It could be washed clear by a combination of peroxide of hydrogen with water. He was sure that this was not artificially produced.

Chorea with Embolism of the Central Artery of the Retina.—Dr. H. M. THOMAS, of Baltimore, reported a case and presented a short review of the embolic theory of chorea. The patient was a girl, aged sixteen, with an unimportant family and personal history. She had never had rheumatism. Seven weeks before admission to hospital right hemichorea developed, and sudden blindness of the left eye came on at about the same time. There was a typical picture of embolism of the central retinal artery. The heart was dilated and there was a systolic murmur. The speaker referred to the literature of similar cases, and said that they were comparatively too few in number to justify holding upon them the so-called embolic theory of chorea.

Dr. KNAPP agreed with Dr. Thomas that chorea with embolism was an unusual event. The embolic theory of chorea did not explain the very large precentage of cases in which there was no evidence whatever of either arthritis or endocarditis. A certain proportion of the cases would naturally be regarded as cortical or subcortical, especially if the symptoms were one-sided.

Dr. DANA said that his experience had lead him to disbelieve in the embolic theory of chorea. He considered that chorea, in the first place, is a disease of the cortex of the brain, the infectious process affecting mainly the capillary circulation of the cortex. In old cases of chorea we get secondarily a degeneration of the arteries and changes in the cortical cells.

New Members.—The following were admitted to membership in the Association: Dr. Allan McLane Hamilton, of New York; Dr. Herman H. Hoppe, of Cincinnati, and Dr. Stewart Paton, of Baltimore.

The annual election resulted in the choice of the following officers for 1902:

Election of Officers.—*President*, Dr. Joseph Collins, of New York; *Vice-Presidents*, Drs. H. T. Patrick, of Chicago, and J. T. Eskridge, of Denver; *Council*, Drs. George L. Walton, of Boston, and George W. Jacoby, of New York; *Secretary and Treasurer*, Dr. G. M. Hammond of New York.

Paul Portal.—John Bartlett says that for a knowledge of the actual relation of the placenta prævia to the neck of the womb, the profession is, without a doubt, indebted to Paul Portal, of Paris. He knew the history of cases of placenta prævia and their tendency to death without delivery; he also knew that to "turn and deliver" might rescue the patient from danger. He had learned that, in some cases, hemorrhage ceased spontaneously. Experience had taught him that, in certain cases, the fœtus not being viable, it might be good practice to detach and remove the placenta in advance of the delivery of the child. The following is the chronological order in which the several authors accredited with the early appreciation of the true relation of the after-birth to the uterus in placenta prævia made their observations: Portal, 1664; Schacker, 1700; Petit, 1723; Giffard, 1730; Brunner, 1730, Smellie, 1747; Levret, 1751; Roederer, 1753; Wessel, 1753; Puzos, 1753; Plattner, 1758, Plenk, 1768; Rigby, 1772.—*The Clinical Review.*

Medical Items.

Contagious Diseases—Weekly Statement.—A report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 13, 1901:

	Cases	Deaths.
Measles	219	10
Diphtheria	155	25
Laryngeal Diphtheria (Croup)		
Scarlet fever	143	25
Smallpox	66	3
Chickenpox	41	
Tuberculosis	267	148
Typhoid fever	24	9
Cerebro-spinal meningitis		4

Self Drugging.—The pernicious habit of self drugging has grown to be a source of untold mischief. It is greatly assisted by the enormous improvements which have been brought about in recent years in pharmaceutical preparations. Thirty or forty years ago medicines were bulky and had to be taken in large doses of generally a nauseating flavor. But now medicines can be taken in small doses and with a minimum of trouble. The columns of the daily press are given up to flaming advertisements, setting forth, in more or less scientific language the various feelings of malaise engendered by hepatic insufficiency and constipation, and the sufferer is assured that if he will take some or other preparation "that tired feeling," or any other of the thousand and one symptoms attributable to dyspepsia or lithemia will vanish like a dream when one awaketh. The advertisements to which we take exception are not quack medicines. They undoubtedly are useful in the condition described under certain circumstances. But the dangerous thing about them is that they induce the public to drug themselves, and, very possibly, to omit to seek treatment for what may not be simply constipation, gout or dyspepsia, but possibly the outcome of malignant disease. This is why we think that such advertisements are in no way right. They are, if not intentionally deceptive, at all events practically so.—*Lancet.*

The Care of Consumptives in the Different Countries of the World.—Of late years no disease has been regarded with so much attention as has consumption. The progress effected in the manner and methods of treatment is well exemplified by the following statistics, compiled by S. W. Hynes, examiner of accounts of institutions in the Department of Finance. From this list it will be gathered that Germany leads the nations with respect to the number of sanatoria for the treatment of tuberculosis, established within a comparatively recent period. "In Germany there have been established, in the last few years, nearly one hundred sanatoria for the treatment of consumptives, with a combined capacity of five thousand. These have been established partly through the government, partly through private charity, and largely through the life insurance companies. In Germany the life insurance companies find it profitable to send their insured who have tuberculosis to sanatoria for treatment, because of what they can save in the payment of insurance money with those who get well, and the deferment of such payment with those whose lives are prolonged. They also profit by the prevention of the spread of the disease. In England, prior to the prevention movement on behalf of the consumptives, there were already hospital accommodations to the extent of about two thousand beds. Since this movement began many new sanatoriums have been opened, and the old ones have been improved. England has probably three thousand beds for consumptives at the present time. In France about two thousand eight hundred beds for tuberculous subjects existed when the present movement began

gan, and sanatoria either have been or are being built since then at Lyons, Paris, Orleans, Bordeaux, Nancy, Lille, Havre, Canet, and Cimiez. The French Government is about completing a sanatorium at Agincourt, at an outlay of over a million francs.

"In Russia, under the leadership of the Czar, five sanatoriums have already been established, and a number are under way. In Italy sanatoriums are being established at Arignano, Padua, Umbria, Naples, Messina, Tarent, Cadore, and Milan. A law has also been passed requiring existing hospitals to set aside wards for the treatment of consumptives. In Norway, since 1897, three sanatoriums have been established, and two are under way, all under the government. A number of private sanatoriums have also been opened. In Denmark a hospital for consumptives, with ninety-four beds, was opened in 1900 for the use of the entire country, and another with 110 beds for the use of the city of Copenhagen only. In Sweden a large sanatorium for consumptives is at present being built as a jubilee memorial. In Switzerland there are already seven sanatoriums for poor consumptives, and a number of others have been projected. In Austria a sanatorium has been established at Alland, and similar institutions are projected in Bohemia, at Machren and at Stiermarck. In Hungary a sanatorium for consumptives is at present being erected as a memorial to the late Queen Elizabeth. In Poland three sanatoriums for consumptives have recently been erected. In Spain, under the leadership of the royal family, a large national sanatorium for consumptives has been opened at Porta Coli. In Portugal Queen Amelia has recently given 20,000,000 reis for the establishment of a tuberculous hospital. In Holland, the young Queen, within a year, has given a large sum of money for the establishment of a sanatorium for consumptives. In Canada, there are as yet but two sanatoriums for consumptives, with a combined capacity of seventy-five beds. In the United States the National Government has established sanatoriums in New Mexico for the treatment of tuberculous marine-hospital patients and for consumptives of the army. The State of New York has at present ten sanatoriums for consumptives under private management, and one projected sanatorium, to be supported by the State. They have an aggregate of six hundred beds. Of the above-named ten, three are situated in the City of New York." The Board of Estimate and Apportionment appropriated for these three institutions, in 1901, $70,000

Safety in Numbers.—*The Lancet* of June 29th treats of the census just taken of the United Kingdom, making the base of discussion the rush of people to towns and the preponderance of the female over the male sex. Our contemporary's shrewd comments run as follows: "For those people who find pleasure in the manipulation of statistics, there is a rich harvest of delight in the recently issued preliminary report and tables resulting from the census investigations of April 1st, 1901. Even the abstract from the report in the *Times* of June 15th is full of figurative plums, for that large class of persons who find interest in such matters. It is curious how many men there are to whom bare figures are a source of interest and gratification; men whose chief pleasure in life is the examination of tables, the comparison of annual statistics, and the detection of minor mathematical flaws. To all such the census returns are, of course, a bonne bouche, the taste of which will linger pleasantly for weeks and months of the present year. Even the less statistical, however, can find in these figures something of interest, and to the medical man certain facts brought out are not unimportant. He ponders over the astounding increase of town as opposed to country population, and on the excess of over 1,000,000 of females over males in Great Britain. Along with the first he places, perhaps, the predominating part that nervous diseases of all kinds tend to acquire in modern nosology, and the second makes him introspective of the position of the modern woman. The remedy for such developments of particular kinds of population is, of course, not in the province of medicine. We are engaged in what sometimes appears to be the paradoxical pursuit of preserving human beings, whether fit or unfit, whether their 'survival' is really for the benefit of the nation which owns them or the reverse. Healthy, or of deficient physical qualities, however, they all play an equal part in the census returns, and the most diseased individual may console himself with the reflection that on paper, he is as fine an item as Mr. Sandow himself. What is to be done for the female plethora? Physical science offers no resource, for in spite of the sanguine recommendations of certain continental physicians, we believe medicine is not yet in a position to offer even the most patriotic of mothers a son when the, at present, incontrovertible course of nature has determined on a daughter. The production of women rather than of men is not to be limited by any means at our disposal; it remains for the political forces of society to dispose of them to the greatest advantage for the nation. English women, happily, have never been wanting in the courage and enterprise of their race, and doubtless in our growing colonies will be found the natural home of many females whom it would be ungracious to characterize as 'superfluous' in Great Britain."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 12, 1901:

SMALLPOX—UNITED STATES

		CASES.	DEATHS.
Iowa, Ottumwa	June 1st to 29th	8	
Kansas, Wichita	June 29th to July 6th	4	
Louisiana, New Orleans	June 29th to July 6th	2

A STUDY OF ITS CAUSES, DURATION, PROPHYLAXIS, AND MANAGEMENT.

By CHARLES L. DANA, A.M., M.D.

NEW YORK.

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL; EX-PRESIDENT OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

I HAVE described in previous articles[1] some of the social conditions and clinical history of the class of patients known as alcoholics, brought into the wards of Bellevue Hospital. The number of these patients has increased from 3,428 in 1889, to 4,100 in 1895,[2] and about 6,000 in 1900.

My present paper gives some further details regarding the development of the inebriate. It shows the rather definite limitations of life of the sot and the periodical inebriate, the maximum capacities of the human body for alcohol, the methods of prevention, the necessity of a special law for the commitment and care of inebriates, and the treatment, temporary and permanent, of this class.

The cases that are brought into the wards include all phases and degrees of alcoholism. I personally studied 350 cases in 1891, and a somewhat larger number in 1892, 1893 and 1895. I found the acute effects of hard drinking to be distributed about as follows: Simple intoxication, sixty per cent.; delirium tremens, ending in recovery, thirty-six per cent; delirium tremens, with complications ending in death, four per cent.

These acute conditions occurred in persons suffering from what may be in general termed inebriety, which took the form of periodical inebriety in about ten per cent., chronic or neurasthenic inebriety in twenty per cent., ordinary drunkenness or besottedness in seventy per cent.

Heredity.—Among 350 patients whom I questioned on this subject, I found that drinking habits existed in one or both parents in all but ten (97.5 per cent.). The father was usually the drinker; in eight cases both parents drank; in one case the mother only was an inebriate. The patients were largely of foreign birth or descent, however, and drinking was the natural habit, so that very great importance cannot be attached to this fact. In another series of 210 cases, the percentage was much lower. Among the total, twenty-five per cent. gave a negative hereditary history. Among thirty periodical inebriates, in two-thirds there was a distinct history of heredity; in fourteen the father drank; in eight both parents drank.

No other point in heredity was systematically investigated; but my opinion is that drinking is largely a matter of habit and environment. The victims of it have always some neuropathic or temperamental bias of which excessive drinking is only the accidental expression.

Occupation.—It is not the day laborers, but the mechanics, artisans, and small tradesmen that furnish the greatest proportion of cases. Drivers, waiters, painters, and liquor dealers supply a very considerable quota. It is the indoor workman, however, who is oftenest the victim. Among 1560 cases I found the following:

Professional men	54
Clerks and salesmen	239
Tradesmen	387
Laborers	589
Drivers	113
Waiters	64
Painters	64
Liquor dealers	50

Among 614 other cases I found this distribution:

Professional men	3 per cent.
Clerks	15 "
Tradesmen	25 "
Laborers	35 "
Drivers	8 "
Others	14 "

Schub asserts that alcoholism occurs relatively oftener in the persons above the laboring classes, and that the "proletariat" are not its worst victims. This is relatively, if not absolutely, the case so far as severe types are concerned. It must be remembered that besides 6,000 cases brought to Bellevue, the police bring to our station-houses over 30,000 cases of drunkenness a year.

Sex.—In a total of 14,301 admissions in the years 1887, 1888, 1889, and 1895, there were 10,470 men, and 3,909 women, giving a proportion of thirty-seven per cent., or little over one-third, women. Eight years ago in 1887), the percentage of women was thirty-two, and it was the same in 1888; in 1889, it was nearly forty, and in 1895 it was thirty-four. There has been, therefore, a slight increase in the proportion as well as absolute number of female alcoholics. In Switzerland, the proportion of alcoholism is four men to one woman.[3] In Russia, the ratio is 3.5 to 1.[4]

Age.—In a series of 210 cases, I tried to find the age at which the drinking habit began. Among thirty periodical inebriates, two-thirds began drinking before twenty and all began before thirty. Among the others, the ratio was practically the same. It is before maturity that the habit is formed, and there is not much danger after the age of thirty. The greater number of cases and of deaths is found between the ages of thirty and forty; next, between forty and fifty in men and between twenty and thirty in women. The death rate, however, increases relatively in women with age. Few deaths occur before twenty or after sixty.[5] Women who become alcoholics die rather of complications, such as pneumonia, neuritis, and exhaustion, without so often developing delirium and then passing into the terminal stage of cerebral œdema congestion, and meningeal inflammation.

[4] S. Sowkanoff, *Rev. Neurol.*, 1899, page 40.

[5] In the Swiss statistics of Schub the deaths occur oftenest between the ages of forty and fifty-nine. The late Dr. Joseph Parrish used to say that the inebriate climacteric was between forty and fifty, but it seems in the hospital classes to come much earlier.

Duration of Life of the Sot—The average duration for men of the drinking habit in serious cases investigated was about fifteen years—the maximum being over forty years. Among periodical inebriates the average duration was nineteen years. In general, it may be concluded that hard drinking can rarely be carried on for more than twenty years, and it generally brings the victim to grief at about the age of forty. There is a certain massive, taurine type of man in whom the capacity to drink seems almost limitless. These creatures have heavy, strong forms, a large muscular system, powerful digestive organs, strong hearts, and usually good brains in the beginning. They have impetuous, aggressive temperaments and strong social instincts, and they often make themselves felt in the community as effective men, though they possess violence of temper, impulsive judgment, and rather defective moral sentiments. When they get to drinking, they develop into sots. They drink moderately, perhaps, in the morning, but keep it up and consume two or three quarts of whiskey daily, going to bed finally in a drunken stupor, but awakening fresh, well, and hungry in the morning. It takes ten or fifteen years to bring on in these subjects the final dementia or insanity, during which time it may be estimated that they drink about two thousand gallons of whiskey. This is, perhaps, the maximum limit for any man, and they reach it usually between the ages of forty and fifty, if their means admit. These men are not drunk except at the end of the day, and often attend to their affairs for years. Some of these continuous drinkers rarely get seriously or noisily intoxicated. One man forty-two years old, said he had been continuously drunk for two years, but had managed to attend to his business.

Striking Examples of Besottedness.—A man of twenty-eight, a dealer in liquors, drank seven or eight pints of champagne and seven to fifteen glasses of beer daily for eight years. Then he replaced the champagne with twenty or thirty drinks of whiskey. Finally, he took up the cigarette habit and this began to finish him. He could no longer stand the drinking, but had an attack of cerebral automatism and began to develop impulsive criminal tendencies.

A man, fifty-five years old, confessed to me that he had been drunk twice a day for three years, making about two thousand intoxications. These were not immoderate or hilarious sprees: he simply got home to dinner in a semi-drunken hebetude from whiskey, and went to bed in a similar condition from beer.

A man of thirty had been drunk every night for a year and a half.

A man of forty-six had been drunk fortnightly for twenty-five years.

A man of forty had been drunk weekly for twenty years.

A man of forty-three had been drunk a thousand times in fifteen years.

A man of fifty had been getting intoxicated daily for about six months in the year since he was seventeen.

It would seem that the capacity for men to get drunk over a thousand times was rare, and that two thousand was the maximum limit in any ordinary inebriate experience.

The Kind of Drink.—The favorite combination for hard drinkers was beer and whiskey, sixty cases; next came whiskey alone, fifty-seven cases; then beer alone, twenty-seven cases; beer and ale, eight cases; ale, eight cases. The total for malt liquors was thirty-eight, and it will be seen that there is no safety from alcoholism in the lauded malt liquors. In twenty-two cases every possible form of drink, including coca wine, absinthe, Jamaica ginger, tincture of soap, and Hostetter's bitters were used.

There is, however, a remarkable absence of alcoholism in wine-drinkers. In fact, I have never seen in this country an inebriate who confined himself to wine, excepting two women who drank champagne.

Prophylaxis.—I have written some things regarding the social and pathological sides of inebriety and also regarding its therapeutics, but I have always hesitated to say anything about the prophylaxis. The subject of the abuse of alcohol has always been considered more a social than a medical one, and though physicians ought to be, and I believe are, the best judges as to the dangers of alcohol and the means of preventing them, their opinions do not carry nearly so much weight as those of the propagandists of some pet social theory or of the officers of a temperance society.

No one, perhaps, has seen more tragic examples of the baneful effects of alcohol upon the human system and upon the human family; and yet I am not prepared to say that alcohol is absolutely and always a pernicious agent, or has not been of use in promoting human progress. On the contrary, I feel inclined to believe that on the whole it has produced more beneficent results that it has done injury, for it must be remembered that its most serious effects are seen in that class whom we call unstable and degenerate—a class from which not much good to the human race could be expected anyway, and which, if it were not injured gratifying its instincts for stimulants, would likely develop pathological symptoms in some other way.*

Alcohol undoubtedly produces degeneracy in the individual and still greater degeneracy in the descendants, but it only exceptionally produces degeneracy in individuals who are originally sane and well-balanced persons. I do not intend to undertake a defense of the use of alcohol but only to state that the proper way of dealing with it is not at once to condemn as a uniform poison a substance, the use of which, despite everything, seems to be holding its own in civilized races, even those which are growing more intelligent. We ought, however, to teach that alcohol is always and absolutely a poison and a surely degenerating agent, when used in excess, and that even when used in moderation it is equally pernicious to a rather large class of human beings. This class must be aware that to use it means disease, insanity, and death, to themselves probably, or to their descendants surely.

The proper function of the physician and of the statesman is to try and limit the use of alcohol and prevent its abuse, and, finally, to rescue, as far as possible, those who have become subject to its influence. But we cannot do this by a propaganda which tries to stamp out at once the production and sale of alcohol and eliminate from the human race the instinct which has been planted and developed there for centuries.

The agencies for preventing and lessening the injury done by alcohol consist in:

1. Teaching. 2. Control of the sale, making it impossible to secure impure alcohol and difficult to secure even good alcohol, and especially difficult for those to whom it is a poison. 3. Avoidance of transmission of degeneration through the marriage of alcoholics. 4. Personal supervision of those who become inebriates.

The physician has particularly potent means to help along three of these lines. As I have shown, the condition of inebriety begins almost always before twenty, and it is during the formative period of youth—between the ages of ten and twenty years—which is the particularly silly period of life, that when parental teaching and admonitory supervision of the physician are called for. If one can keep a man from hard drinking until he is twenty-five he is not likely to

*Alcohol is beyond any doubt a food, having, according to physiological chemists, about half the caloric value of fat.

form bad habits, and after thirty years he is almost safe.

As regards marriage, the physician has less to say, and yet we know that children born of well developed inebriates are pretty sure to have some neuropathic taint and that the family, unless very richly infused with new blood, will perish in the third generation.

As to the personal control of inebriates, I have a particular word to say. There is no more difficult problem presented to the physican than that of what to do with the periodical or more or less chronic inebriate. His history is that he at first perhaps reforms for a short time under the solicitation of his friends or family, then relapses again, and has very likely taken some form of "cure"; relapsing again, he continues to waste his substance, and impair his physical health, moral stamina, and business position by further drinking. In despair perhaps he is now brought to the physician with the request either to cure him or to put him where he can do no harm.

In this State we are practically helpless in such cases. If the alcoholism has reached that pitch where the man is insane we can sometimes lock him up as such; but when he clears up, as he may in a few months, he soon gets out again and resumes his debauches. He can be committed as an inebriate only for a short time. My own belief is that the most effective mode of relief would be to have a law passed enabling us to commit the inebriate for from one to three years, never less than one, and better, in many cases, three years. The objection to previous laws has been: 1. That the inebriate has been committed for no specified time, and, having gotten over his spree, he in a few months insists upon getting out and succeeds, only to return to his former course. 2. That the inebriate gets liquor at the institution to which he is committed.

To obviate the first defect, our present insane law might be altered so that it would read that the individual should be committed as an inebriate and unable to care for his affairs, for a period of three hundred and sixty-five or more days, as the case might be. He could then be placed in a licensed State or private hospital, or in some licensed asylum organized for this purpose. The Connecticut law is said to be a good one. This contains provisions enabling the authorities to commit an habitual drunkard to an inebriate asylum for not less than four nor more than twelve months, and if the person is found to be a dipsomaniac the term of commitment is to be for three years. Individuals may also voluntarily commit themselves for these periods of time.

The second difficulty is harder to overcome. When we get good laws and successfully commit the patient, he proceeds to get drunk at the very places to which he is sent for cure. And the more specifically the sanitarium is devoted to inebriates, the easier it seems to be in some instances for the inmates to get what they want. Therefore, some special responsibility and penalty should be enforced upon persons who have charge of these institutions, or who, under a future inebriate law, are allowed to receive patients.

Treatment.—The treatment of all that class known as the inebriate is at present of two kinds, the ideal and the practical. The ideal treatment is supervision of the case in an institution, ensuring absolute abstinence from alcohol in all forms for at least one year. Further personal supervision and watchfulness are needed for two years. After that period the patient is reasonably safe unless he is quite young. Unfortunately, this treatment can rarely be carried out. As already stated, the law does not permit the legal commitment of inebriates, except voluntarily, and then only for a short time.

Under present conditions we have to resort to all kinds of makeshifts. The most common is the "cure." These cures have all the same basis. They consist in the use of strychnine, atropine, and apomorphine or some other nauseant. With these are combined tonics, laxatives, full feeding, and the psychical influences exercised on the patient by the procedures of the cure. These are very important, and illustrate how much better a charlatan can sometimes manage feeble and credulous minds than can the most honest physician. The man who takes a "cure" feels a little pride in the experience, and rather wants to show that he has done a wise thing; he has invested his money, and he doesn't want it to be shown that he has been fooled. He has made a special effort of will in submitting himself to reform, and if the patient has some force of character left he may be helped for a long time. But I should say that, as a rule, the patients relapse, and that relapses are more frequent since the vogue of the "cures" has become less. Many of these cures have dropped out of sight because the prestige has gone and the psychical influences fail.

Still, often the best thing a drinker can do is to take some kind of a "cure," under the care of his own physician. It must be understood that the treatment is a cure, and it should be planned to last a year.

The patient should stop drinking and usually smoking, and take for three weeks a mixture of nux vomica, capsicum, and cinchona.

℞ Tinct. nucis vomic ..... ℥i.
Tinct. capsici ..... ʒi.
Tinct. cinchon. rubræ ..... ℥v.

Mft. Sig.: One teaspoonful three times a day, increased by 20 drops daily to half an ounce three times a day.

The maximum dose should be continued for a week, and then reduced as it was increased.

At the same time two drachms of bromide of sodium should be given daily in cases marked by much nervous irritability and insomnia. The patient *should be fed well and very often, and avoid getting tired or hungry.* When the desire for drink comes on he should be told to take two drachms of the above mixture, to which is added 1-120 grain of atropine sulphate and he should fly to hot milk or beef tea to relieve his fatigue. Tonic baths should be added if possible.

After two weeks rest from medicine, the course should be repeated, the patient all the time reporting weekly to his physician.

After the second course, a month's interval can be allowed, when it should be repeated again, and so on till the end of the year.

All this is very difficult to secure. Inebriates are impulsive, unappreciative, self-confident, and impatient of restraint. But this is all that one can do outside of an institution.

50 West Forty-sixth Street.

Arterial Degeneration and the Tendency Thereto.—Henry Walter Syers thus sums up his article: 1. To determine the presence of degeneration of arteries it is not enough to examine the radical artery only, but the state of other vessels, especially the brachial and the temporal, must be taken into account. 2. Arterial degeneration in many cases is due to an inherited vice, often connected with gout, and is often the weak point in the constitution, determining early death. 3. Care and watchfulness should be exerted to postpone the onset of the malady as long as possible. 4. Only in those cases in which the disease is induced by syphilis or by indulgence in drink can treatment be expected to produce any great improvement. 5. More attention than is customary should be devoted to the investigation of the special liability of any particular case, as the latent tendency to this vascular change is not only widespread, but is fraught with the greatest risk of premature death.—*Treatment.*

PRIMARY RESECTION OF THE INTESTINE FOR GANGRENOUS HERNIA; REPORT OF TWO CASES OF SUCCESSFUL JOINING BY LATERAL ANASTOMOSIS, WITH THE CONNEL SUTURE.

BY THOMAS H. MANLEY, M.D., PH.D.,
NEW YORK,
VISITING SURGEON TO THE HARLEM HOSPITAL.

THE joining of the divided ends of the intestine, directly after resection of the gangrenous intestine in strangulated hernia by successful methods constitutes one of the most brilliant achievements of modern aggressive surgery.

It is essentially a measure of very recent development, although for centuries back we find evidence of attempts at enterorrhaphy with varying results, from the notable case of Ramdohr in 1727, by invagination; and that of Deverger, who employed a desiccated segment of calf's trachea, in 1763, as a support in the interior of the gut, the patient recovering and the tracheal-ring being thrown off, per rectum, on the twelfth day.

Richter vainly endeavored, by experimentation, to devise some means to close the hole left in the sloughing gut. Littré was the first to resect successfully several feet of the intestine in gangrenous hernia, though a fecal fistula was left to remain through life.

In the early part of the present century, extensive experiments were made in France, on the intestines

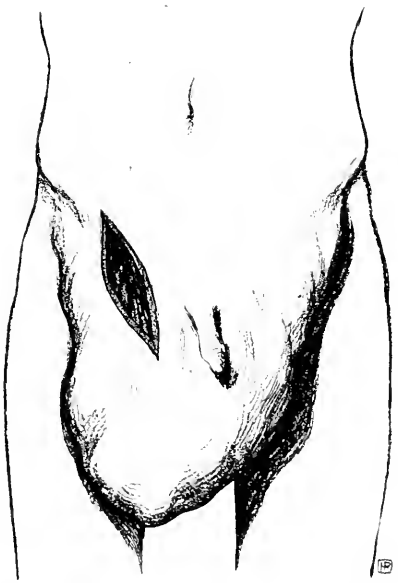

Fig. 1.—Oblong Incision upward through Poupart's Ligament.

of lower animals, with a view to solving the problem of intestinal joining in disease or injury. The names of Jobert, Lembert, and Geily have become historical in this connection. But the disastrous results following the application of their deductions on the human being, by Reyhard and others, led to its general condemnation. Anæsthesia came in 1848, but for nearly forty years it provided no improvement in the operative treatment of strangulated hernia, as we are assured by a statement of the late distinguished surgeon, Dr. Frank Hamilton, in 1880, that the mortality from strangulation, at that time remained about the same as in former centuries—viz., 70 per cent.

After the introduction of antiseptics on scientific principles by surgeons, at about 1880, intestinal surgery came into prominence and was revived on a large scale and placed on a secure foundation by German surgeons.

In 1888, at the International Medical Congress at Washington, Dr. Nicholas Senn submitted his remarkable and epoch-making essay on an "Experimental Study of Intestinal Surgery." Although this contribution was based entirely on experimentation,

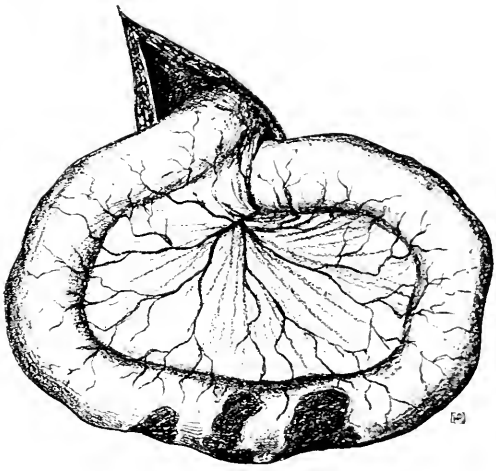

Fig. 2.—Gangrenous Ulceration of the Intestine in Hernia prior to Resection.

it must be regarded as the most valuable, ever before or since submitted, on the surgery of the intestine. It constitutes, practically, the foundation rock on which we have been later building. At the same time, this illustrious surgeon gave us the decalcified bone-plate, something up to that time unrivalled as an approximating support in anastomosis or enterorrhaphy.

Celerity in manipulating has always been regarded as of prime importance in all operations on peritoneal structures. The Senn plate in skilled hands abbreviated the operative period.

The art of intestinal surgery embraces the general principles of mechanics, and hence the effective technique of intestinal junction presupposes a skilled practiced hand and the employment of mechanical aids. The Senn plate fulfilled several theoretical requirements. But it did not dispense with the suture, nor was its adjustment by any means a simple and rapid procedure, except in well-trained hands.

In 1893 Dr. John B. Murphy invented an anastomotic disc for uniting the ends of the intestine, or anastomosing their walls; it may also be employed for canalizing the walls of the stomach or gall-bladder. This button is the very acme of human ingenuity, never before equalled, and probably it never can be improved upon as a mechanical aid. Like the Senn plate, in experienced hands, it will shorten the time of jointing the intestine a few moments; like the plate, too, its adjustment invariably calls for the employment of the suture. Its employment, is by no means an easy task for the inexperienced. It has been used on a larger scale and with far greater success in internal lesions of the intestine, than any other mechanical device. It may be

utilized in areas quite inaccessible to any other means, and under various circumstances can be substituted by no other expedient.

In 1892, Dr. M. E. Connell published a brief description of a mode of effecting an end-to-end enterorrhaphy by the employment of a suture. He claimed for it simplicity, security, and safety; and, moreover, that it might be applied, as a rule, as quickly as any of the uniting contrivances then in use. In Baltimore, in 1894, the doctor very kindly explained to me its technique and later sent me several specimens and models illustrating its application.

But it had not yet stood the test of a trial on the human being. Surgeons passed it over in silence, or by general deprecation, because its employment was in violation of some of the most cherished tenets of the surgery of the intestine. Silk suture was recommended; the suture is *continuous:* it must pass through *all* the layers of the intestine, and leave the knots on both ends *outside.*

Notwithstanding its apparent imperfections this suture impressed me as the simplest and best yet devised. In order to test the matter, I made several experiments on the dog, making two or three sections of gut at same time, then joining or anastomosing the ends. In twenty-nine dogs, I anastomosed the divided gut laterally in eighteen and lost none. In eleven, I jointed by end-to-end enterorrhaphy and lost two. My experiment convinced me that this suture was all that Connell claimed for it; but, in order to attain ideal results and obviate the lurking danger of the dead space in the mesentery, in end-to-end union, we must, when at all practicable, obviate

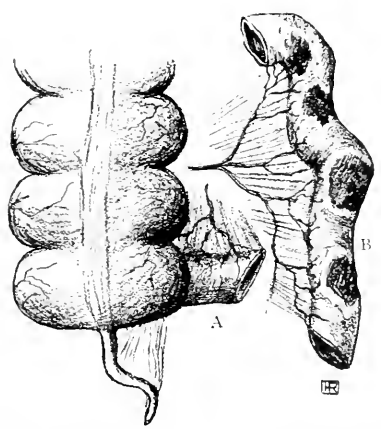

Fig. 3.—A. Incision through afferent end of intestine oblique to long axis. B. Resected segment so divided as to preserve long mesenteric border.

this by a lateral anastomosis, in every instance of resection for strangulated gangrenous hernia.

Dr. Senn has personally informed me that he has come to regard the suture as the best uniting material in joining the intestines, and I understand that Dr. Murphy does not recommend his button in gangrenous hernia.

Dr. Gregory Connell has devised a very ingenious modification which obviates some of the objections of his father's suture. At Columbus, Ohio, the doctor fully described to me its application on the sheep's intestine. By this plan the knots are turned in. But the method impressed me, though remarkably ingenious, as very complex and as no improvement on the original.

Artificial Anus and Primary Resection in Gangrenous Hernia.—After the division or resection of a damaged coil of intestine in the approximation or jointing of the ends, we are confronted by the same difficulties in restoring continuity that we find in a bone-shaft, in a complete fracture with displacement. There is no mechanical impediment to the complete reduction and retention of the separated fragments, but to ensure this without impairing or destroying the vascular supply is sometimes quite impracticable. And so it has been found, in gut-jointing, that while

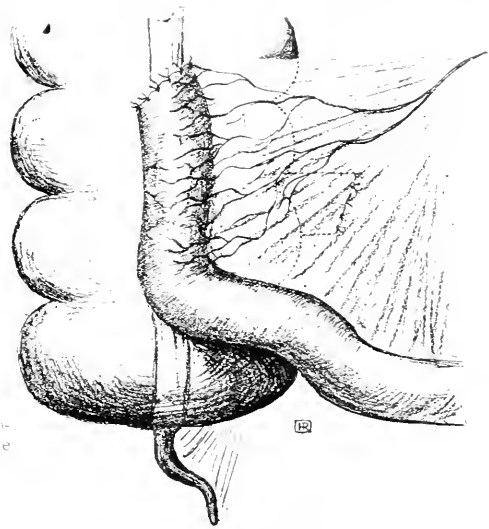

Fig. 4.—Ileo-colic lateral anastomosis after resection in gangrenous strangulation.

there have been a great number of devices invented to effect this, one after another, with few exceptions, they have been set aside, not because they did not effect excellent coaptation, but because they clogged the lumen of the bowel or strangulated the vascular supply in its walls.

In strangulated hernia death rarely ensues until after various degrees of gangrene, torsion, or stenosis of the intestine, either before reduction by kelotomy or after it, often from incomplete timid surgery.

In former times, the operation for the treatment of strangulation was a hotch-potch, unscientific procedure. An incision was made, the ring divided, the unopened sac and all pushed up *en masse* into the abdomen.

The older operators had a horror of hemorrhage and peritonitis. The majority of their patients speedily sank after operation; usually, it was said, from shock or peritonitis, while in fact they went down from an unrelieved torsion, stricture, or perforation of the intestine. Only one phase of gangrene seemed to warrant the production of an artificial anus, viz., when sphacelus or mortification was complete, or the bowel was already widely opened. It sounds strangely these times to note the advice of some writers who say that "in strangulation, with intestine of doubtful vitality, the best place for it is in the belly." But artificial anus has a large immediate and remote mortality. In six cases coming under my own care none survived a fortnight. In three cases no relief came, as there was a twist in the bowel above.

It was only very recently that surgeons could nerve themselves to undertake primary resection. Precon-

ceived convictions from misleading instruction and a consciousness of a want of technical knowledge made them hesitate or operate under great disadvantages.

Then the question of *primary* or *secondary* resection came up. It was said that patients suffering from gangrenous hernia are so exhausted as to bear so formidable an operation as resection very badly, especially, as one noted writer tells us, that "in any event, it will take from one and a half to two and a half hours to complete an intestinal resection."

But whatever line we pursue, provided, of course, our patient is not in a moribund state, we must freely and widely divide the parts not only up to the ring, but above it, in order that *all* the elements of obstruction are well cleared; then, in order to isolate the mortified parts, remove them, and secure an efficient enterostomy, we must resect the dead from the living tissues and pass a row or two of sutures to secure the open intestine in position, in artificial anus. Now, should it occupy any more time freely to expose the

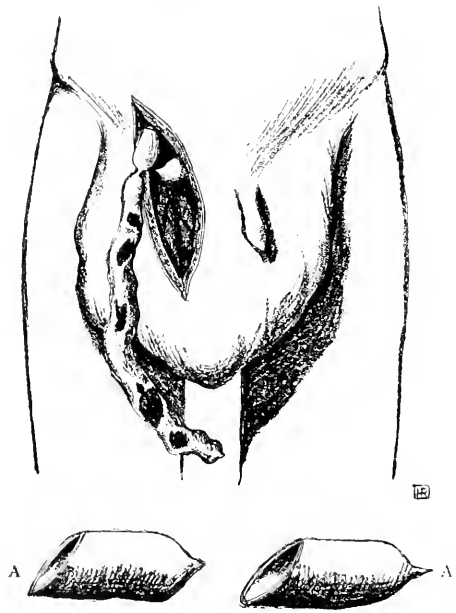

Fig. 5.—Gangrenous hernia with spontaneous amputation of efferent end of intestine. A, Resected ends of intestine prior to enterorrhaphy.

intestine, resect the gangrenous segment, join the healthy ends, and return the gut to the abdomen? Everything being in readiness, a large incision freely exposing the deep parts, a suture jointing by the Connell method may be made by trained hands, in from 15 to 30 minutes. One not familiar with the technique of enterostomy should not undertake it except in an emergency.

Effective enterostomy for gangrenous hernia involves a laparotomy with the kelotomy in practically every case. A large incision is necessary through the site of obstruction for the double purpose of freely drawing the bowel down and, what is equally important, of affording an easy return of the jointed intestine.

Against this free division of the parts, it has been objected that it intensifies shock. However, practical experience proves precisely the contrary, viz., that from the moment the constriction is divided and the gut liberated, the pulse slackens and becomes fuller, the respirations are deeper and more regular.

It is therefore evident that, everything considered, in the formation of an effective artificial anus, one must explore well up over the constricting areas, cut away the necrotic mass and suture the ends of the intestine outside the peritoneal cavity. The essays of Kendall Franks, Lockwood, Rydygier, and McCosh all agree that the economy of time in making an artificial anus is quite insignificant.

Modes of jointing after resection of gangrenous hernia.—Bishop up to 1885 had collected thirty-three different modes of anastomosing the intestine, and Greig Smith in 1896 was able to add thirty more. Nearly all authors occupy common ground in the application of general principles in the jointing of the divided gut. For example, until very recently, and from the very remotest period, end-to-end junction—circular enterorrhaphy—or the re-establishment of the alimentary current over the long axis of the bowel, has been the general rule in resection for gangrenous hernia.

The Lembert suture, Depuytren's or some modification of it, has been regarded as the only one, at all, warranted. Catgut, or some other absorbable suture, had the preference. The great problem was to provide some means that would at one and the same time secure against leakage and not impede the vascular supply to the ends of the divided gut. The Murphy button, no doubt, in a larger degree than any other device fulfils the purpose. But in a bowel crippled by strangulation, with an imperfect vascular supply and a languid alimentary current, the button, or any other apparatus, is at a disadvantage; it may lead to a kinking, may become clogged, or cut unevenly through the intestine.

The uniting discs set aside, in gangrenous hernia, we turn to, first the suture material, and secondly, its mode of application. Suture material here should be fairly fine, strong, and resistant. Mr. Greig Smith, for general intestinal suture prefers fine twisted Chinese silk; but the fairly fine and strong domestic braided or twisted silk will answer for all purposes. An absorbable suture is not safe here, for the reason that in some cases the peristaltic motion commences to put a severe strain on the new joint about the third day after suturing, and unless the delicate plastic adhesions are well re-enforced at this period, the whole bond of union, or part of it, may break down, and large fæcal escape follow. Silk may be easily sterilized and can be employed with a round needle. Catgut requires a Hagedron needle, and tears the delicate serous investment of the intestine.

The Connell is the only continued suture ever heretofore employed, which passes through *all* the coats of the intestine. Moreover, it is a longitudinal suture employed in an oblique or circular enterorrhaphy. On theoretical grounds it was rejected because, it was claimed, "any suture passing through from the mucous to the serous cavity must convey infection and every needle hole become a fistulous opening."

Mr. Greig Smith believed that Connell's was an excellent suture "for the first perforating row," but he stated in his well-known work, that he would not describe it as he was not aware then—1896—that it had ever been employed in the living human being. It has been objected, too, that a running or continued suture was bound to loosen and allow escape on collapse of the bowel. But a healthy vascular intestine does not collapse on completion of the suture; on the contrary, it fills, distends, and begins in a measure to functionate at once.

In *circular* enterorrhaphy, though I believe it even then the simplest and most secure, the inherent mesenteric defect remains in the Connell suture, as in any other; hence it would seem that its great value consists in its application, in combination with *lateral*

anastomosis or enterorrhaphy, in gangrenous hernial resection, when this is practicable.

I am aware that there appear from a speculative view of the subject, several

Weighty Objections.—We must close *three* breaches in the intestinal structure instead of one; there are two diverticula left in the ends of the intestine; the alimentary—or fæcal—current must be deflected and discharged from one segment to another. This it would seem must disturb the anatomical arrangement of the intestine and interfere with regular physiological persistalsis. But theoretical speculation must give way to the demonstration of facts, as has been the case since the first great advances in abdominal surgery began.

The late Mr. Greig Smith, the most noted authority on the surgery of the abdomen in his time, writing on this phase of the subject, said that "it has been proven, so far as restoration of function is concerned, it matters little how the divided intestines are joined as regards their axes; that is, whether end-to-end or side-to-side, the question is almost entirely a practical one." He, however, expressed his opinion "that there was nothing to prove that lateral approximation is more successful in its immediate results than end-to-end junction." He believed that in the lateral, we had to consume time, in closing the ends, that might suffice for a circular suture.

The crowning advantage of lateral joining or anastomosis is the preservation of an abundant vascular supply to the traumatized parts. It obviates the tendency to annular, cicatricial contraction, which may follow a circular enterorrhaphy.

Inequality in the calibre of the intestines to be joined offers no inconvenience. As the borders of the new portal are firmly held apart by the silk suture until solid healing is complete, ultimate stenosis is improbable.

The difference in time, in closing three apertures or one, is so insignificant as to count for nothing. In fact, in comparison with one of the latest approved methods for joining by circular enterorrhaphy—the Czerny-Lembert—without question the Connell suture in lateral anastomosis can be applied in much less time.

Report of Cases of Intestinal Resection in Gangrenous Hernia, with Lateral Jointing by Connell's Suture.—My own experience in resection of the gangrenous gut in strangulated hernia, in which the Connell suture was employed to joint the intestine, is limited to two cases, one private and one hospital case. The former has been briefly reported in the *Annals of Surgery*, May 12th, 1897.

As it was the first case so treated, and as now four years have elapsed since the operation was performed, and there were several special features of interest in the pathology of the case, as well as in the operative manipulation and its ultimate results, it will bear repetition here.

History of First Case.—On November 11th, 1896, I was called by Dr. C. F. W. Horn, of this city, to see a Chinaman, twenty-eight years old, suffering from strangulated hernia, right inguinal. The strangulation had lasted four days and repeated efforts had been made by taxis to reduce it.

The scrotum was enormously distended and inflamed, and at its base showed signs of pointing, like a huge phlegmon, with a necrotic patch on the surface, near the base. The whole mass was wanting in resonance and fluctuated.

The patient's general condition was very bad. The abdomen was largely distended, hard, and everywhere sensitive. He had persistent, fæcal vomiting, with great thirst; and, though being freely plied with morphine by injection, was constantly moaning. His pulse was 140 and thready, the temperature 104° Fahr. in the mouth. The extremities were covered by a cold, clammy sweat. His symptoms pointed to a general toxæmia, with peritonitis, and that he was close to the moribund state

Preparations were rapidly made for an operation to relieve the strangulation, which we were quite certain would be complicated by gangrene.

A long, deep cut exposed the sac. On opening this, a large quantity foul-smelling liquid with fæces came through. On widening the incision, a long coil of the ileum came through it with one end completely cut off by pressure at the ring. By carrying the incision up and exposing the ring, the other, or proximal end, was found nearly eroded; so that on lifting the free coil, this gave way, and we had here

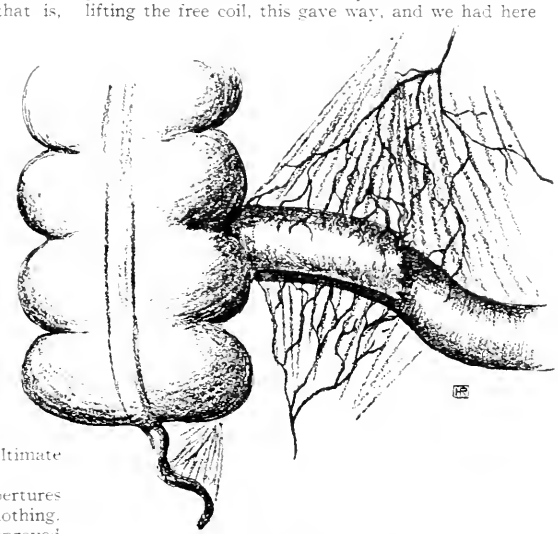

Fig. 6.—Ileo-iliac lateral anastomosis after resection in gangrenous hernia.

a spontaneous excision of twenty-seven inches of gut. On making traction on the divided ends at the ring, it was found that one was in close relation with the cæcum, as it could not be brought out.

Now the parts were thoroughly cleansed, and the incision was carried well up through Poupart's ligament, freely exposing the cæcum. The amputation of the ileum was made five inches from the ileo-cæcal junction. From both of the projecting ends a little more than three inches were cut away; the ends were closed and a side-to-side, ileo-ileo anastomosis was made with strong silk suture, by the Connel method. As there had been so much sloughing over the line of incision, except for about two inches above, it was left open; one tampon of sterile gauze was left in the scrotal segment, and one passed down on to the anastomotic junction of the intestine in the peritoneal cavity. Over all, abundant dry dressings were applied.

After the operation was completed, the man's general condition was much better than when we began. The day following his temperature was 99.4°, pulse 90, with all signs of danger past.

The next day the dressing and the bed-clothing were found freely soaked by a dark, gangrenous-smelling discharge from the incision

The packing was removed daily for one week. Until the end of ten days, a small quantity of fæcal-smelling fluid escaped from the wound. After this it ceased. In three weeks the wound was soundly healed and he was up. He returned to his work at the end of the fifth week.

This young man before operation, for eight years had a hernia which a truss would not control. He was of a slight, spare frame. It is now just four years since the resection was made, and ample time has elapsed to determine the ulterior effects of loss of nearly a yard of the small intestine on his digestion and general health, and the effects of so large an incision in the way of favoring another hernia. He occupies the same premises now which he did four years ago, and he has since on several occasions been exhibited before medical classes and societies. His digestion is perfect and vigorous; he has gained forty pounds in weight, and though he never wore any prophylactic support, he has yet had no trace of hernia.

CASE II: *Right Inguinal Hernia, Strangulated and Gangrenous, Resection of Intestine, Ileo-cæcal Side-to-side Anastomosis, Jointing by the Connel Suture.*

Patient, a male, twenty-eight years old, clerk; always enjoyed good health till present accident.

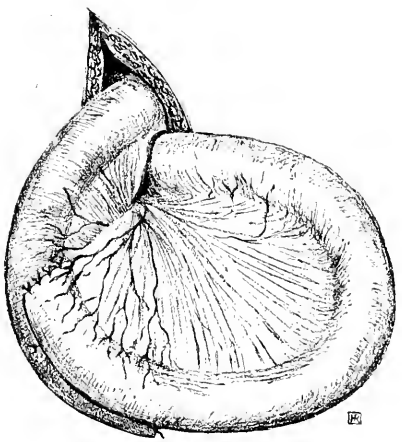

Fig. 7.—Lateral anastomosis after intestinal exclusion before reduction.

On August 24, 1900, shortly after dinner, while moving a heavy chest, he was seized with severe pain in the abdomen and right side. Soon the colic became most acute and exhaustion followed. A physician was called, who discovered that he had a strangulated hernia. He never had hernia of any description before this one appeared. An ambulance was called and he was sent to the Harlem Hospital. When he reached there his symptoms were not regarded urgent. This was at 5 P.M. He was under the influence of morphine and fairly comfortable. The house physician made moderate taxis on his admission, but failing, returned the patient to bed and applied an ice-bag over the hernia.

The patient passed a restless night, receiving four hypodermic injections of morphine in twelve hours. In the middle of the forenoon following, renewed efforts at taxis were made without avail.

At this time all his symptoms became more accentuated; but he had yet had no vomiting. At three in the afternoon he was first seen by me. At this time he showed signs of shock, he was of a marble pallor, with a weak but not rapid pulse—94—temperature 101°, in great pain and very restless. In the right groin he had a large tumor, extending well down into the scrotum. This was highly sensative, and was resonant on percussion.

Everything being in readiness, he was prepared for operation and anæsthetized. The incision was commenced high up, on the axis continuous with the inguinal canal. On opening the sac there issued forth a foul, gangrenous smelling fluid. Nearly the entire loop of intestine was in a state of gangrene. Pressure, punctures, and the hot-water test, proved beyond question its total death.

Now the deeper stratum of the incision was carried through the stricture in the ring and Poupart's ligament; with this, the internal epigastric artery was opened. The ends of the vessel were closed and the strangulation was removed, when the parts were critically examined.

It was found that it was the terminal segment of the ileum which was involved, the gangrene extending well up to the cæcal terminus. This case impressed me as another one favorable for lateral anastomosis, and also implantation of the ileum in the cæcum. Here the cæcum had a long mesentery, and hence was easily manipulated outside the abdomen. Nineteen inches—forty-eight centimetres—were resected of the ileum, care being taken to leave a long mesenteric attachment to the retained ends of the intestines. On dividing the intestine, it was found filled with clots and fluid arterial blood. This was squeezed out of both lumina in large quantities.

The two ends of the divided intestine were now closed with interrupted silk suture, after inverting the edges. The next step was to carry the ileum well up on to the cæcal wall, and temporarily adjust it, preparatory to lateral jointing. The ileum was led up to its place of mooring in such a manner that, for a distance of about five centimetres above and below the anastomotic aperture about to be made, its long axis would lie in the same plane as the long axis of the cæcum.

Then, with the anchor sutures in position, a careful measurement was made and the cæcum was first opened on its side, midway between the long-band and the mesentery. The ileum was opened in the same manner, viz., along its long axis, on the side between its convex border and the mesenteric attachment. The opening was about three inches—eight centimeters—long. Now the interior, or mucous, lining of the bowels was well cleansed up to the point of compression on either side.

Realizing at once the marked difference in the resistance of the caput-coli and the small intestine, the suture was so applied as to take a deep grip, and leave at the same time a considerable border of the serosa, in order to sustain with safety the severe strain of the intestine at this point. Connell's suture was applied in less than ten minutes. Finally, in order to rest fully assured that the jointing was ample, four interrupted silk sutures were applied. The compressing loops of gauze, to control the fæcal current, were now removed, when immediately the anastomosed parts filled with gas and fluid, passing along from one intestine into the other with no sign of leakage.

At this stage the whole mass was thoroughly washed with sterilized water, and the jointed parts were carefully returned to the abdomen. Now, a Bassini operation was superadded for the hernial cure, and the scrotal wound was closed, but the opening above Poupart's ligament was left with a gauze fold in position over the cæcum, as in the preceding case.

The patient, following morning, very comfortable. He had had no vomiting. Pulse 90 and small; tem-

perature 99°. From this date, progress was steady and uneventful. On the third day he requested an enema, but this was refused. On the fourth day he had a large spontaneous motion, which consisted largely of a black coffee-ground material. The appetite was ravenous. The wound was dressed daily. On the third day a fæcal-smelling fluid appeared in the wound. On deep pressure a hissing of gas was heard through the incision. On the twelfth day all tamponing was removed permanently. On the twentieth day the wound was solidly healed.

In six weeks from the day of operation the man returned to work at his desk. Two months after the operation, October 29th, he weighed eight pounds more than he ever did before. Digestion was perfect and the man has recovered his full strength and vigor.

This second and last case presents several highly interesting features.

First, as to the clinical history. Here we discover strangulation, the *first time* the hernia appears.

Secondly, as to the symptoms. At no time were they of such a violent character as would lead one to the suspicion of gangrene. No vomiting neither before nor after operation. The marked anæmia or rather exsanguination resulting from the large hemorrhage into the bowel probably was due to laceration of the vessels in the submucosan, at the point of strangulation.

Thirdly, as to the behavior of the wound. The leakage of fæcal fluid, for some days after free peristalsis began, suggests the great necessity of always leaving a free vent for any peccant fluids which may escape from the new joint, in the early stages of healing.

Fourthly the anatomico-physiological aspect of the case, the loss of the ileo-cæcal valve, the lateral joining of parts widely dissimilar in structure and function; this was a veritable test-case to demonstrate practically the reliance which we may place on the security of this suture with lateral implantation, rather than in circular enterorrhaphy, or end-to-end apposition, the cardinal and fundamental value of which seems to be derived from the quickness of its application and the conservation of the freest possible vascular supply to the injured parts.

Since the foregoing was written another case, calling for resection of the gangrenous intestine for strangulated hernia has come under my care, the patient sinking shortly after laparotomy.

The patient was admitted into Harlem Hospital at one P. M. on May 9th, 1901. He was a man fifty-five years old, American, of temperate habits. He had usually enjoyed good health, but for several years had a reducible inguinal hernia on the right side. About noon on May 8th the hernia came down in large volume. Unaided by medical assistance, he made very many unavailing efforts at reduction during the afternoon and night. The following morning he had severe abdominal pain, and in the meantime the hernia had become much larger.

His condition on admission to hospital was bad. He had marked abdominal distension with severe pain and muscular rigidity. There was no vomiting. The pulse was 122 and thready, the temperature 103°, respiration 24. He was weak and was very pale. He was able to urinate, and the urine on chemical examination was found normal. There was a large fulness in the right inguinal region, not extending far down into the scrotum. There was no impulse on coughing; the tumor was tympanitic on percussion.

The patient was prepared for operation, ether being administered. A long incision was made from three inches above the internal ring to the base of the scrotum. When the sac was divided a deeply congested knuckle of intestine came into view. On division of the constriction and opening of the peritoneal cavity there was a free issue of a dark colored, foul smelling fluid. Upon my drawing on the distal end of the extended intestine, there came down a widely distended gangrenous segment, the mesentery of which was thickened and œdematous. After the application of various tests this was was found to be in a gangrenous state, but not sphacelated. A segment, thirty-eight inches in length, was resected and the divided intestine was laterally joined by the Connell suture. The whole procedure from the beginning of the operation to the closing of the wound occupied but thirty-five minutes. In this case, as the one previously recorded of resection, the intestine was widely distended with blood, so that on its division more than a quart poured out of the open lumina. By a milking process large quantities could be pressed out from both ends.

After anastomosis the intestine was reduced, and a gauze wick was introduced through the wound for a drain.

The patient came out from the anæsthetic well, and expressed himself as much relieved. At five P. M. he had a large bloody evacuation by the rectum. He now had considerable thirst and was given

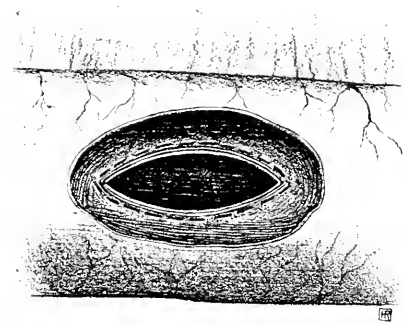

Fig. 8.—Connell suture in position in lateral jointing after intestinal resection

diluted milk with whiskey. At 7.30 he was seized with nausea and vomited a large quantity of blood and almost immediately after he expired.

Post-Mortem Examination—Eighteen hours after death; rigor-mortis was well marked, with evidence of extreme exsanguination. The wound was re-opened. No hemorrhage had taken place into the peritoneal cavity. The continuity of the intestine had been re-established. The anastomosed segment was resected and on testing was found to be completely water-tight. Death was caused by exhaustion, succeeding internal intestinal hemorrhage, produced by the violent, forcible taxis inflicted by the patient's own hands.

It would seem almost incredible that one could inflict so much damage to the bowel by his own hands; but it is nevertheless a fact. For example, about a week after this case came into my hands, I was called at midnight to operate on what was supposed to be another case of strangulated hernia, as the patient had about all the symptoms appertaining thereto. He had worn a truss, but now the mass had suddenly increased in volume. He vainly tried to reduce it, but without effect. He had severe abdominal pain, vomiting, and muscular rigidity with marked exhaustion; but on operation no trace of a hernia of any kind was found, only a sarcomatous testis, which had burst through the

tunica vaginalis as a result of the man's efforts "to reduce it."

This case was remarkable, inasmuch as it had been diagnosed as "strangulated hernia" by a physician of large experience. For months it had been treated with a truss as a rupture, and it was only when the misguided patient used violence upon himself that the classical symptom of "strangulation" became apparent.

THE USE OF SULPHATE OF COPPER IN AFFECTIONS OF THE CORNEA AND IN AFFECTIONS OF THE LID OTHER THAN TRACHOMA.

By J. HERBERT CLAIBORNE, M.D.,

NEW YORK.

It is my purpose in this paper to present the results of my experience in the treatment of corneal affections and affections of the conjunctiva other than trachoma, by sulphate of copper.

I am aware that the use of sulphate of copper has been and is recognized as the classical form of treatment in trachoma, whether the trachoma is restricted to the lids or whether it is associated with keratitis and pannus; I do not desire, therefore, to bring up the time-worn subject of bluestone in the treatment of trachoma before my readers. Within the last three years, however, it has been my fortune to observe excellent results from the use of bluestone in other conditions than those which are recognized by constituted authority. In order that the subject may be brought out clearly, I propose to detail in brief the history of a number of cases

Case I.—A boy of feeble intelligence, aged ten years, was brought to me suffering from intense photophobia and pain in his right eye. Inspection revealed the existence of a superficial keratitis, which was restricted to the upper half of the cornea, and consisted in infiltrated points and a slight degree of pannus. On examination of the upper lid no evidences of a true trachoma presented themselves; the upper lid, however, was somewhat swollen and exhibited the appearance of what I am accustomed to call "velvet conjunctivitis." This term describes more nearly than anything else I can think of the condition to which I refer. The lid presented a velvety appearance, and the villi of the velvet projected to some extent from the conjunctiva, which warranted me in describing it as I did. The lower lid showed no signs of trachoma whatever.

The boy had been treated with yellow oxide salve, atropine, boric acid, and hot applications—the usual treatment for such cases. All these had been tried with no benefit whatsoever resulting from their use. At that time I was not thoroughly convinced of the utility of bluestone in such cases, and I proceeded to treat him for several days along the same lines. To this end he was sent to the hospital. No benefit resulting, I concluded to use the bluestone, treating him for six or eight weeks, with the result that his eye became perfectly well, the cornea cleared up entirely, and the conjunctival appearance which I have described disappeared. The result of this treatment was marked, and benefit was experienced after the first application. Advantage was taken of this fortuitous result, and the treatment was pursued carefully and persistently. I repeat, there was no sign in this case of a true trachoma, and it could not by the greatest stretch of liberty or license be described as such. There was a superficial keratitis with some degree of pannus. The bluestone acted quickly, safely, and happily. I do not think that any other form of treatment would have resulted, to say the least, in so rapid a recovery. During this treatment no atropine was used, the eye was simply bathed with ice-cold water with a little salt dissolved in it.

Case II.—A young lady, of florid complexion and fair skin, was seen by me five years before the following incident. She suffered from headaches. Examination of her eyes discovered compound hypermetropic astigmatism associated with a number of small corneal opacities producing some irregular astigmatism.

She gave the history that since early childhood she had been accustomed to have repeated recurrent attacks of inflammation of the eyes. I diagnosed recurrent phlyctenular keratitis, with a mental reflection that the condition was due to systemic causes which are recognized as classical. During my first treatment she developed a mild attack of keratitis, for which, without having any specific reason at that time, I employed bluestone, with the result that the condition rapidly subsided; I drew no deductions, however, from this fact. Five years later she was brought to my notice again, having spent that time in Europe at school and in traveling on the continent. Her last sojourn was at Rome, where she had repeated attacks of headaches and phlyctenular keratitis.

This second time she entered my office with an acutely inflamed cornea, pericorneal injections, pain, photophobia—in short, the symptoms of an acute attack of superficial keratitis.

On everting the upper lid I discovered a swollen, succulent condition of the mucous membrane, suggesting the velvety conjunctivitis already referred to. I immediately explained to her that within the last few years it had been my custom to treat such cases not in the usual manner, but by the application of bluestone. She agreed to put herself entirely in my hands, and I immediately commenced the use of the bluestone. The first application produced so marked a benefit that she became convinced of its efficacy and demanded its continuance. To make a long story short, she was under my care three months, and the bluestone was applied two or three times a week throughout the entire period; the bluestone was continued after all the corneal inflammation and infiltration had almost entirely disappeared.

The conjunctiva of the upper lid retained its characteristic appearance almost up to the time of her dismissal; at that time, however, I could safely pronounce her relieved of the condition so far as the upper lid was concerned. The corneal infiltrations had diminished to a very great extent so that they could no longer be seen by direct inspection with the naked eye; the eyes took on a very much more healthy look and the patient expressed herself as being satisfied.

In this case there was no evidence of trachoma, and in view of the preceding history and characteristic appearance of the cornea nothing short of a diagnosis of repeated attacks of phlyctenular keratitis or superficial keratitis could possibly have been made. There was nothing in the appearance of the young woman indicating a scrofulous diathesis which is ordinarily assumed to be present in these cases, and in a guarded manner I said to her parents that while I was not able to state definitely that her affection was not due to the condition known as scrofulous diathesis, I was nevertheless of the opinion, from my experience of the last two or three years, that if the condition from which she suffered could not be eradicated it could at least be controlled by the application of bluestone. I therefore suggested the use of the bluestone on each occasion of the reappearance of the inflammation, and its application in the manner in which I had used it.

The patient returned to Rome, taking with her

several sticks of the bluestone ground after the American custom. She said that she would tolerate no other form of treatment.

Case III.—A little girl, a clinical patient, has been for a year or two accustomed to present herself at the New Amsterdam Eye and Ear Hospital at different periods with acute inflammation having attendant pain and an indolent ulcer of the center of the cornea. It is well known that these patients are difficult to cure and are subject to recurrent attacks of acute inflammation. The girl had been treated in the ordinary way—atropine and yellow oxide salve—with the result that at the end of a certain length of time the acute symptoms would subside. She would remain away until the eye became inflamed again, and then she would return. Throughout this treatment she was subjected to the use of atropine and the discomfort of a dilated pupil. I ceased the use of atropine and yellow oxide salve entirely and used bluestone, applying it as usual.

The upper lid presented on each occasion the same appearance already referred to. Immediately on the application of the bluestone there was a beneficent result, so much so that I determined to make use of it continuously. On each occasion she was relieved by the use of bluestone alone, no other treatment being used.

This child has not been cured, but the symptoms have been relieved very much more quickly under the use of sulphate of copper than under regular treatment. The benefit is most marked and the patient returns with alacrity for its employment.

Case IV.—A young woman of florid complexion presented a case of herpes zoster of the right side of the forehead; the cornea became involved, as is usually the case.

After the acute symptoms had disappeared the ulcer of the cornea was treated in the ordinary way—atropine, yellow oxide salve, and hot applications. At length the ulcer filled up and deep infiltration resulted. This infiltration was directly in the center of the cornea; it was exceedingly painful, as is usually the case in this affection, and most unsightly.

This patient was under the care of one of my colleagues who did not share my views on the subject of sulphate of copper. During his absence in Europe she fell under my care and I took the liberty of applying the bluestone to the lids in the usual manner, and the beneficial result was marked; immediately the eye commenced to feel and look better, the cornea cleared up, the blood vessels which had almost covered the upper part of the cornea disappeared, and the entire set of symptoms improved. About that time my colleague returned from Europe and she passed from under my observation. Within recent time it was my fortune to see this patient once more and she came under my treatment. The infiltration of the cornea had increased and a marked convergence of the eye had resulted in consequence of the deteriorated vision. Treatment with the bluestone for two weeks produced a most beneficial effect upon the general appearance of the individual; she herself said that this treatment is of more value than any other form of application. The upper lid in this case presented the same appearance I have described. My colleague has at last decided to continue the treatment and the case is progressing well.

Case V.—An old woman, aged sixty years, upon whom an operation for cataract had been performed, presented herself at the New Amsterdam Eye and Ear Hospital with superficial ulcer of the cornea. The ordinary treatment with atropine had been applied without any beneficial result. Bluestone was used in the customary manner and was followed immediately by improvement. This treatment has been continued at the suggestion and by the request of the patient independently of my own views, benefit being received on each occasion. She remains away whenever she feels better, always coming back, but never remaining under treatment long enough to be entirely relieved.

Case VI.—A young woman, aged twenty-three years, a demi-mondaine, presented herself for treatment with an infiltration of the center of the cornea, attended by intense pain, photophobia, and lacrymation. The customary treatment by atropine and hot applications was employed with but slight relief. There was a great deal of pericorneal injection. The atropine was discontinued immediately, the hot applications to be used if desired, and bluestone applied three times a week. The benefit was marked and immediate; the patient made an almost complete recovery, when a set of unfortunate circumstances carried her from the sphere of my influence and she has since passed from my observation.

The result of the treatment was so marked and so definite that she pronounced herself in favor of it, and it was also remarked by colleagues who were present.

I have, for the last two years, persistently made use of this treatment in all forms of inflammation of the cornea that are recurrent and are not interstitial in character. I have not, however, employed it in the so-called rodent ulcer or in the serpent ulcer of Saemisch. I conceive that it might be of advantage in the rodent ulcer, but while it may be of use in the serpent ulcer of Saemisch, I can see that it is not so definitely indicated in deep inflammations of the cornea as in superficial inflammations and infiltrations. I have not employed it in superficial injuries of the cornea, such as abrasions and superficial wounds. So far as curing inflammations of the cornea is concerned I have observed it to be of advantage in those cases in which the conjunctivitis is associated with a succulent, velvety appearance of the upper lid. This I have generally found to be present in persistent corneal inflammations that are of superficial nature.

These cases, I think, suffice to show the value of bluestone under the circumstances I have outlined. I desire to recite a case of a different nature, however, in which its effect was most marked.

A little boy, nine years old, had recurrent phlyctenular keratitis from babyhood. Over his right cornea was a scar so dense that he was scarcely able to count fingers; over his left cornea there was also a macula less dense in character, but occupying the center of the cornea. He was old enough to go to school, but had been kept away on account of his inability to see letters. I regret to say that I did not take accurate measurements of his vision on the occasion of my visit, but was told there was no use in sending him to school on account of his diminished sight. He was accustomed to have repeated attacks of exacerbations and remissions in the inflammation with pain, photophobia, lacrymation—in short, acute attacks of superficial keratitis.

I examined his lids, both during these attacks and during the intervals, and on no occasion was I able to detect the characteristic appearance on the upper lid indicating the employment of bluestone. Nevertheless I determined to try it in this case.

At the end of two months the infiltration about his cornea commenced to lessen and six months afterward the infiltration in the right eye was so slight that he was able to count fingers at fifteen feet, and with his other eye, with which he had not been able to see letters at all, he could count fingers

at thirty feet. According to the statement of his parents he was able to read with some facility.

It may be said that there was absolutely no indication for the use of bluestone in this case and that its employment was purely empirical; however that may be, the result was most marked.

The best manner of using the bluestone to obtain satisfactory results will be referred to later on.

It has been my custom also in little children suffering from photophobia and lacrymation, the characteristics of acute phlyctenular attacks, to apply bluestone. This is done without the subsidiary use of atropine; yellow oxide salve may be used upon the lids to prevent their closure in the mornings. It has been my routine custom to make use of this treatment in such cases. In older subjects who present the symptoms of phlyctenular keratitis it is also my custom to use this treatment, and the results have always been consistent with the results in other cases.

It is not difficult for me to conceive that some one of my readers may reply that what has been presented is nothing new. I do not pretend that it is anything new, except in so far as the use of bluestone for the cure of cases in which it has not heretofore been employed is concerned.

I have already referred to its use in trachoma and it is rather singular to me that the benefits obtained from its employment in this affection have not earlier suggested its use in keratitis. If it has already been employed by others in cases such as I have indicated I am unaware of the fact. The cases which I have detailed are characteristic and I have not time to outline all of those which have received treatment at my hands. For a very long while in the treatment of trachomatous pannus I had been accustomed to use atropine associated with bluestone. It was but a short time ago that I came to the conclusion, at the suggestion of some colleagues, that atropine was of no value but was rather detrimental inasmuch as it produced paralysis of accommodation and increased the annoyance by reason of the dilated pupil and made the patient generally uncomfortable.

The dilatation produced by the atropine and the paralysis of accommodation are annoying to children and more so to older persons who are capable of appreciating the loss of the power of accommodation.

I conceive, therefore, that the point which I have endeavored to bring forward is one of considerable importance in ophthalmology. If cases of superficial keratitis, ulcer of the cornea, and lid affections can be cured without the use of atropine, something has unquestionably been gained. I am also not unaware that there are many who will argue that the same result may have been obtained by the use of yellow oxide salve, calomel, or some other form of innocuous application between the lids.

In reply I would only say that the use of yellow oxide salve on the inside of the lid for certain conditions is very good, nevertheless in phlyctenular keratitis and particularly in marginal keratitis I will state with confidence that in my hands no such results have been obtained through its employment as have been obtained by the use of bluestone. Its effects are more marked, more lasting, and decidedly more satisfactory to the surgeon and to the patient.

It has been held that the use of yellow oxide salve on the interior of the lids, employed according to the usual method, produced beneficial results from the irritation of the surface of the cornea, increasing the blood supply and the rapid interchange of fluids in the interstices of the cornea, causing, therefore, a more rapid absorption of infiltrated material. I have no other explanation than this to offer for the action of bluestone in such affections, except the following:

Bluestone is unquestionably a disinfectant, an antiseptic, germicide, and to a most marked degree astringent. While it produces similar effect upon the corneal infiltration as does the yellow oxide salve, it is to a greater degree astringent and at the same time it disinfects, cauterizes, and renders antiseptic the lids and so removes the sources of infection of the cornea. I do not think that we have definitely appreciated the rôle that an inflamed, irritated, succulent lid plays in infecting and reinfecting a corneal infiltration, and I attribute the benefit which I have observed in the treatment of such cases in some respect to the irritating effect of the bluestone, but more to the disinfection and cauterization of the lid.

I shall now call attention to the beneficial effect of bluestone in certain chronic affections of the lids; in short, to chronic conjunctivitis, which is attended by thickening of the lids with reddening of their borders—also to cases of chronic dacryocystitis. As types I will recite one or two cases.

A young man, thirty-one years old, had been afflicted with thickened, reddened lids since childhood. There was marked blepharitis with falling of the eyelashes. There was little or no secretion, but there was a feeling of heaviness and heat.

I explained to the patient that the treatment would take at least nine months, that it would be painful in character, and that his assistance would be of as much value in the case as my treatment. If he desired to undertake the treatment I would guarantee a complete recovery. This bold promise was accepted and treatment was begun. Bluestone was applied in the regular way three times a week for nine months. The lashes whenever necessary were epilated, and nitrate of silver was applied where there was a raw or bleeding surface. Yellow oxide of mercury was used at home and zinc was applied twice a day. At times there would be lapses of treatment from the bluestone in which case the eyes would invariably become worse and the patient would return for more treatment with the bluestone and a renewal of faith and enthusiasm.

At the end of twelve months he was rewarded by being discharged with eyes of normal appearance.

It may be urged that some constitutional treatment and the general mode of life, together with local treatment, the epilation of the lashes, and the use of yellow oxide salve and zinc cured this case. To this I can only reply that I do not think it is true. Whenever the bluestone was withdrawn the eyes would become worse; the patient came to recognize this himself and would return every time after his faith had failed temporarily.

I have used bluestone in cases of this description as a routine treatment for the last three years and I can say definitely that it has produced results such as I have never seen under any other form of treatment. It was valuable where silver could not be used for a prolonged treatment on account of producing argyriasis of the conjunctiva. I have found boric acid to be of no practical service in such cases. It is distinctly palliative, not curative. Solutions of zinc sulphate are of subsidiary assistance but will not produce a cure.

Although not strictly within the limits of this paper, I cannot refrain from mentioning the results obtained from bluestone in the treatment of chronic dacryocystitis associated with slit canaliculi and attended by chronic conjunctivitis.

The treatment by probes of this condition is so very unsatisfactory that it has been practically laid

aside by authority. Reliance is chiefly placed upon the sulphate of zinc, used in mild solution.

The obstinacy of these cases is well recognized. The theory of the profit derived from the use of zinc is that the solution flows into the sac and duct and acts as an astringent upon the swollen and thickened mucous membrane. It is safe to say that the bluestone acts in a similar manner. But the benefit derived is far more rapid and striking than that from the use of zinc.

I have on hand, at present, four patients with chronic dacryocystitis at the Vanderbilt Clinic, whose comfort has been greatly increased and whose lives have been made more tolerable by this treatment. Of course they have not been cured, for there is no cure for this condition.

I have been accustomed to apply the bluestone secundum modum three times a week until inflammatory symptoms have disappeared and then according to circumstances, being guided by the wishes of the patients who return when they feel the need of it.

Any remedy which ameliorates this uncomfortable condition should be accepted. I feel quite certain that any surgeon who uses it in these cases will obtain the corroborative testimony of the patient concerning the beneficial results.

I have also used sulphate of copper in acute attacks of pink-eye with most satisfactory results—a rapid diminution of the inflammation and a cure certainly as rapid as that under any other form of treatment. Of course bluestone is indicated in the follicular form of conjunctivitis which is not trachoma, but that disease scarcely comes within the limits of this paper. I am, therefore, compelled to regard bluestone as indicated in all forms of chronic conjunctivitis and in those other classes of cases which I have outlined.

Before closing these references to the use of bluestone I wish to indicate certain conditions of the conjunctiva, which I am not aware have been described specifically, but which have probably come under the designation of conjunctival catarrh and chronic conjunctivitis. I refer in the first place to the condition accompanying recurrent attacks of superficial keratitis which I have here described as villous or velvety conjunctivitis. I have seen another form of conjunctivitis which may very aptly be described as granular, inasmuch as there is the appearance of grains on the conjunctiva, resembling the fine grains of sand on the finest grade of sandpaper. Bluestone is certainly indicated in these cases.

As an instance; A boy ten years of age, suffered from blepharospasm and slight headache. He had an error of refraction which was corrected. Fowler's solution of arsenic was given. The upper lid presented the characteristic appearance of "sand conjunctivis;" the eyes felt heavy and gritty. This form of conjunctivis persisted and it was months before he recovered, in fact, on examination some short time ago there were still some slight evidences of the sandy appearance. I have frequently found this condition associated with anæmia; the upper lids are far from presenting the red look of ordinary conjunctivitis; in fact the conjunctival surface is pale.

I do not consider it necessary to carry these remarks further. I have at least outlined my views in the cases detailed.

And now a word concerning the application of the bluestone. The ordinary stick of bluestone which is found at opticians', the round pointed stick, should not be used; the point is apt to be broken and will likely wound the conjunctiva. The stick should be ground in the form of a parallelogram and then inserted into a porte-crayon.

In making this application the surgeon should sit in front of the patient, the patient's face being toward the light. A metal probe should be wound with cotton and laid in a basin of water which the patient holds in his hands under his chin. The patient is directed to look down and the upper lid is turned. The stick of bluestone is then run underneath the upper lid between it and the ball of the eye, so that that portion of the upper lid is reached which is next to the ball. Except in severe cases of trachoma I never apply the bluestone to the outer surface of the upper lid. This, in my opinion, should not be washed off with water. The upper lid is now drawn gently down and the bluestone is stroked along the cul-de-sac of the lower lid. The surplus bluestone is now washed off with water, and is removed from the cul-de-sac of the lower lid by use of the cotton-wrapped probe.

I desire to lay stress upon the necessity of applying the bluestone to the upper lid on the under surface between it and the ball; unless this is done, in my experience the results are not so good.

I am opposed to the use of camel's hair brushes. While I am not absolutely able to attribute any case of infection to the use of brushes that have been used in other cases, such a possibility appears to be most reasonable. Brushes are rarely disinfected in bichloride; they are cleansed in hot running water. A brush is a dirty thing in any case and cannot be thoroughly disinfected. Although their use is countenanced in clinics, I cannot conscientiously recommend them.

I may sum up my conclusions in this matter as follows. Copper sulphate in the form of the solid stick is indicated:

1. In all acute attacks of inflammation of the cornea in which there is thickening with a succulent velvety appearance of the upper lid.

2. In all recurrent attacks of superficial keratitis in which the same condition of the upper lid prevails.

3. In infiltrations of the cornea which are the result of preceding inflammations, associated with the same condition of the upper lid.

4. In maculæ of the cornea in children and adults which have occurred a reasonable time after an inflammation, whether the upper lid presents the characteristic appearance or not.

5. In chronic conjunctivitis attended by thickening of the lid associated with blepharitis.

6. In chronic dacryocystitis (particularly in those cases in which the canaliculus has been slit) attended by chronic conjunctivitis.

39 West Thirty-sixth street.

Deaths Due to Wild Animals in India.—A satisfactory decrease in the number of people and cattle killed by wild animals in the Punjab is shown by the report for 1900. The ubiquitous snake is, of course, far and away the worst of these ills, but in a province where considerably more than half a million people must inevitably die every year, in the ordinary course of nature, it is reassuring to find that only 893 people received their quietus from snake bite. It is curious to note that more deaths from snake bite occurred in houses, than either in the fields or in the jungle. The only other human deaths from wild animals were those caused by mad dogs and mad jackals which numbered 29. Regarding cattle, 762 were killed by leopards, and 94 by wolves. It seems strange that no mischief should have been caused by tigers or bears—perhaps they are being killed off too fast. During the year in question, 1,374 wild animals were slaughtered, including 11 tigers, 186 bears, 184 leopards and 99 wolves. Moreover, 13,272 snakes were killed.—*Indian Lancet.*

NEEDED REFORMS IN THE MANAGEMENT OF YOUTHFUL AND INSANE CRIMINALS.*

By WILLIAM GLASSELL SOMERVILLE, A.B., M.D.

TUSCALOOSA, ALA.,

TRUSTEE OF ALABAMA INSANE HOSPITALS.

Some one has said "the prisoner is a moral and physical patient, more or less curable, and we must apply to him the great principles of the art of medicine. To a diversity of ills we must apply a diversity of remedies." Thus it is to the physician and not to the moralist and lawmaker that society will have to look for the repression and correction of vice and crime.

There are two great causes which make every man what he is, viz., heredity and environment. That the moral disposition for good and evil, including criminal tendencies, love, hatred, courage, and cruelty, are transmitted from the parents to their children, or from one generation to another, has been proved, and is as firmly believed by all scientific men as the fact that parents transmit to their children the physical qualities of beauty, color of eye or hair, and shape of nose. As there are exceptions to the physical transmissions, so there are exceptions to the moral transmission of qualities. Occasionally we find a son or daughter totally unlike either father or mother in physical appearance, while on the other hand we find one child, the so-called "black sheep of the flock," who evinces marked criminal tendencies. The question naturally arises, why this difference? Why does not the law of heredity hold good? My answer to this would be that these are apparent exceptions and that from some former generation this moral obliquity comes, latent it may be for several generations, but retaining its potential energy and perhaps nurtured by external influences, until finally it makes its appearance in some unfortunate one, handed down to him as a legacy from an erring ancestor. The mental and moral deficiency in the parents does not necessarily manifest itself in the children in the same form. In one generation we find insanity, in another epilepsy or some other neurosis; some have strong criminal tendencies, or are defective in moral sense—in short, they are degenerates. As Maudsley so aptly expresses it, "there is a destiny made for a man by his ancestors, and no one can elude, were he able to attempt it, the tyranny of his organization."

There are many who recognize hereditary influence in animals, but fail to recognize it in men. Occasionally we find in a litter of puppies that there is one which differs entirely from the parents and others either in color or mental qualities. When we wish to buy a horse, a cow, or a dog, we are governed to a great extent by the qualities of their parents—in other words, their pedigree is the controlling influence. The history of a remarkable family, known as the "Jukes," has been traced through seven generations, including 709 persons, every one of whom was a thief, robber, murderer, prostitute, or lunatic.

When I speak of environment, I use the term in its broadest sense, including education in general; mental and moral, religious and social, physical and political conditions. Hereditary influences are coeval with the beginning of mankind, and will be felt to the end. Environment and education are the powers and circumstances which are to a greater or lesser extent modifying heredity in the present and future generations. By proper environment and education along with social reforms, ancestral tendencies to vice can to some extent be overcome, and much can be done to prevent the increase in our defective and degenerate classes. With every mental act and every deed there is a decomposition or molecular change in some of the brain cells, followed by rapid repair; but this repair is not an exact reproduction of the brain tissue—a modification is produced in its substance, the character of the modification depending upon the quality of the thought or act performed; that is, if any given act or deed is good, that modification which takes place in the reproduction of the brain tissue is such that this same portion of the brain will in the future more easily generate thoughts and deeds of even a higher standard. On the other hand, if any given thought or deed is evil, the modification which takes place is of a different character, and in this case we have brain tissue which, should occasion arise, is more likely than before to generate thoughts of a lower standard. Thoughts and deeds of a good or evil character are produced by education and environment, being of course modified to a great extent by hereditary influences; and it is in this way that proper education and surroundings elevate the functions of the brain so that it will generate thoughts and deeds far nobler, less selfish, and more moral than it was wont.

The object of all law is to protect society and to prevent crime. It is the criminal whom we should consider and not the crime alone—the crime is merely one symptom of a defective organization. No two criminals are, perhaps, exactly similar, hence each should be dealt with differently. We should examine each criminal just as we examine a man with physical disease, observing his heredity, his physical and psychological characteristics, and his environments, taking a complete clinical history of him so far as possible, to determine whether his defect is congenital or acquired, and whether it is capable or incapable of rectification and improvement.

Prof. Ferri, in his work on "Criminal Sociology," makes the following classification of criminals:—"1. Criminal madmen; 2. Born criminals; 3. Criminals by contracted habit; 4. Occasional criminals; 5. Criminals of passion."

The class of "criminal madmen" consists of those who commit crimes while insane, and includes the subjects of homicidal mania, moral insanity, and some cases of paranoia. They are, as a rule, hereditary, though latent until the periods of puberty and adolescence, or later in life. These cases shade imperceptibly into the "born criminals," who are degenerates—true moral imbeciles; their moral insensibility is such that they have no self-control against crime; their crime is a neurosis. "They are like a painter in his studio dreaming of his next masterpiece," and are unaffected by punishment, which is a natural risk of their occupation, just as miners or those who handle dynamite do not reckon the dangers to which they are exposed, and are uninfluenced by the terrible accidents which so frequently befall their fellow workmen. The criminal insane and the born criminal are not *morally* responsible, inasmuch as they are congenitally defective, and hence not responsible for their degeneracy. Yet these two classes as well as all classes of criminals are *legally* responsible, for social defense requires that they be placed where they cannot commit crimes, and for so long a period as they would be dangerous to society. The only question would be, where?

The "criminal by contracted habit," as a rule, commits his first crime in youth, almost invariably

*Read before the Medical Association of the State of Alabama at its annual meeting, April, 1901.

against property and through moral weakness, being induced thereto more by environment than by hereditary tendencies. These cases are liable to relapse if their environments are unfavorable or if associated with hardened criminals. The "occasional criminal" commits crime on account of his physical and social environment, and does not relapse, if temptations are removed. The "criminal of passion" as a rule commits a crime against the person, done either in anger or in defense of honor, usually not premeditated, but with a precise motive and openly, and followed by remorse. These cases rarely relapse. Prof. Ferri says that "the true difference between the born and the occasional criminal is that, with the former, the external cause is less operative than the internal tendency, because this tendency possesses, as it were, a centrifugal force, driving the individual to commit crime, whilst, for the occasional criminal, it is rather a case of feeble power of resistance against external causes to which most of the inducement is due." And again, he says, "with the born criminal it is, above all, the lack or the weakness of moral sense which fails to withstand crime, whereas with the occasional criminal the moral sense is almost normal, but inability to realize beforehand the consequences of the act causes him to yield to external influences."

In the management of youthful criminals, we must recognize the fact that we have different types—one class, however, shading almost imperceptibly into the other; and it is evident that the treatment should not be the same for each class. Furthermore, the *criminal* should be considered and not the *crime*, for crime is a symptom of a condition—an act, a transgression of the laws, by an individual, who is a degenerate, either insane or a moral imbecile, or who is impelled by social environments, or by habit or by passion.

The "born criminal" we cannot hope to reform. Individuals of this class, no matter what their crime, if it can be shown that they are born criminals, as indicated by their frequent relapses and defective moral sense, should be confined indefinitely and forever. They are unable to adapt themselves to their social environments, and should be removed. They should be kept separate from those who can be reformed, for there is no doubt that, although young, they will have a bad influence over other criminals. Much can be done in the way of reformation of the "criminal by contracted habit" and the "occasional criminal."

When a person is placed on trial and all evidence pro and con has been given, the duties of judge and jurors should cease when the latter have rendered their decision as to the guilt of the accused. If the person has been found guilty, the verdict in all cases should be "To be confined until reformed." What good is accomplished by sending a prisoner up for thirty days, or to the penitentiary for three months? The young man and the occasional criminal come in contact with the habitual criminal, and there can be no question as to the results. They are turned loose upon society more degenerate morally, more hardened, and more adept in crime than they were when admitted, perhaps again to fall into crime. All transgressors against the law should be given *indeterminate* sentences, and as far as possible classified according to their moral responsibilities. Every one should be compelled to work, and receive instruction in branches of literature or rudiments of learning, and in ethics, philosophy, and physical culture, according to his requirements and natural ability. The duration of his confinement should depend on his moral character and disposition to work. When the authorities of the institution, who must be competent judges, decide that any one is entitled to a release, such a person could be given a parole and be required to report by letter to the authorities at specified intervals. Any violation of parole should, without trial, subject him to further incarceration. The Elmira Reformatory in New York State, which was opened in 1876, has practically this system. What are the results? Eighty per cent. never relapse into crime, and the average time of detention is twenty-two months.

The question of unfixed or indeterminate sentences is thoroughly practical and scientifically correct for adult as well as for youthful and insane criminals; for, as Villert says, "when the measure of punishment is fixed beforehand the judge is like a doctor who, after a superficial diagnosis, orders a draught for the patient, and names the day when he shall be sent out of the hospital, without regard to the state of his health at the time." For economic reasons, also, the indefinite sentence is preferable. In New York State it is estimated that the average detention of the inmates of the Reformatory, where there is an indeterminate sentence, is twenty-two months; whereas, of those committed to the penitentiary for the same crimes and for fixed periods the average imprisonment is five years—the former being an immense saving to the State.

A penal agricultural colony for the detention of certain classes of young criminals is one of the best methods for social defense, as well as a means for their reformation and change of environment. Outdoor labor tends to secure physical and moral health, and every degree of labor from light to severe occupation can be obtained. This method would be specially applicable to those who have committed their first offense and are not too defective morally. It would avoid the bringing together of all classes of criminals in places where many of the most promising ones are bound to be made worse by association with the born and incorrigible criminal.

For some offenses, such as bodily injury, blows threats, and slander, committed by criminals of passion or occasional criminals (the former are not criminals in the strict sense of the word) there should be a reparation of damages by fines, reduction of wages, or forced labor. This reparation of damages should be made a penal substitute—to obtain which it should be unnecessary to enter the civil courts.

As there is no distinct line of demarcation between sanity and insanity, so the type of some criminals merges into that of the insane madman. As Maudsley expresses it, "there is a borderland between crime and insanity, near one boundary of which we meet with something of madness but more of sin, and near the other boundary of which something of sin but more madness. A just estimate of the moral responsibility of the unhappy people inhabiting this borderland will assuredly not be made until we get rid of the metaphysical measure of responsibility, and proceed by way of observation and induction to sound generalization concerning the origin of the moral sentiments, the laws of their development, and the causes, course, and varieties of moral degeneracy."

In the class of criminal madmen, I would call special attention to the subjects of *paranoia*, which is defined by M. Allen Starr as "a chronic form of delusional insanity, characterized by fixed and systematized delusions, which dominate but do not impair the intellect." The majority of the doubtful cases of the criminal insane are paranoiacs. Guiteau was an example of this unfortunate class, whose legal murder was a blot upon science as well as upon humanity.

I am of the opinion that the criminal insane should be confined in separate asylums, on account of the demoralization which this class exerts over the harm-

less insane; and, because dangerous, they should be more securely confined; for it is a fact that the ordinary insane hospital is not sufficiently secure for the confinement of many insane criminals. The management and discipline of the "criminal madman," furthermore, are necessarily different from those of the harmless insane. I believe too that the criminal lunatic asylum is the place for those unfortunate degenerates who inhabit the "borderland" between crime and insanity. Whether sane or insane, if they are dangerous to society, social defense demands that they be confined. The criminal insane asylum will prevent the hue and cry which is raised whenever a criminal is "acquitted on the plea of insanity." There should be no acquittal—if he is insane or if he has no moral sense, no matter how slight the crime, and if he is dangerous to society (and he is), he should be confined until he has recovered or is no longer dangerous, which in many cases would be for life. This class of cases needs caring for more than the harmless insane.

There is another class of evil-doers, who are no more responsible for their condition than they are for the color of their hair or shape of their noses, or than the lunatic is responsible for his insanity. I refer to the dipsomaniac or the periodical drinker. This condition is an inherited disease—a neurosis. The father or mother or some ancestor was neurotic, or insane, or a drunkard. It is his inheritance, his birth-right. If he had not been an inebriate he might have been insane or a criminal. If he had been insane, we would confine him in a lunatic asylum; if a criminal he would be sent to the penitentiary; but if, perchance, inebriety is his inheritance, we do nothing either to protect him or society, unless he infringes upon the majesty of the law, and then he is treated as any other criminal. There is great need of legislation along this line. The physician or family should be enabled to control the cases legally. Moral, social, and religious influences and detention where they cannot obtain alcohol, do more to cure these cases than medicine. The State, in order to care for chronic alcoholics, might tax the saloons enough above the present rate of taxation to provide the necessary funds. There is need, also, for legislative enactment for the care and supervision of the children of criminal and drunken parents, whose environment from infancy is such that when they have reached maturity, they are too frequently hardened criminals. There is no doubt also that the press publication of details of murder is itself a great source of crime, by suggestion; and such should be restricted by law.

The points which I wish to emphasize cannot be better expressed than in the words of Mr. Arthur MacDonald in his work on "Criminology:" "*First.*—It is detrimental financially, as well as socially and morally, to release prisoners when there is a probability of their returning to crime; for in this case, the convict is less expensive than the ex-convict.

"*Second.*—The determinate sentence permits many prisoners to be released, who are morally certain to return to crime. The indeterminate sentence is the best method of affording the prisoner an opportunity to reform, without exposing society to unnecessary dangers.

"*Third.*—The ground for the imprisonment of the criminal is, first of all, *because he is dangerous to society*. This principle avoids the uncertainty that may rest upon the decision as to the degree of freedom; for upon the last principle some of the most brutal crimes would receive a light punishment."

Whatever the remedy of crime, the cause must be studied first; and let us as physicians put our shoulders to the wheel, and by virtue of our knowledge of the laws of heredity, and by virtue of our studies of the physical and psychological state of the criminal, and by virtue of our knowledge of the degrees of responsibility, obtain just and scientific laws for the management and betterment of these unfortunate people. Let us study the causes and the prevention of crime in a philosophical manner, that the destiny of future generations may be changed.

Epigastric Pain.—H. W. Bettmann calls attention to the fact that paroxysmal pains in the epigastrium, variously called gastralgia, cardialgia, gastrodynia, and gastrospasm, are frequently caused by gallstones and cholecystitis. The special features of paroxysmal epigastric pain due to gallstones are these: the attacks may occur independently of the taking of food; they often occur at night, four to six hours after the last meal; they are very likely to follow the ingestion of acid drinks or alcoholic beverages; they are often accompanied and followed by tenderness over the gallbladder; between the attacks the gastric functions and the gastric secretions may be perfectly normal. This clinical picture is almost pathognomonic of gallstones. Many patients affected with gallstones complain for months of epigastric pains, coming on daily after meals and of variable intensity and duration. It should be laid down as a clinical rule that gallstones should be suspected whenever patients complain of regularly recurring or paroxysmal severe epigastric pain, coming on several hours after eating, and when a careful examination of the secretions and digestive functions of the stomach reveals no abnormality.

It cannot be too strongly asserted that when several examinations of the stomach fail to reveal any abnormality of function we should seek elsewhere than in the stomach for the prime cause of the symptoms. Persistent epigastric pain may come from pelvic lesions and occasionally from eye strain. It is found in young chlorotic girls, suggesting the existence of gastric ulcer. The special features are the chlorotic background, the absence of nausea or vomiting, the localization of the pain in the median line, normal or diminished acidity of the gastric juice, spots of marked tenderness corresponding to the seat of pain, and, most important of all, the rapid moderation or disappearance of the pain on the administration of Blaud's pills and Fowler's solution.

Still again, epigastric pain is often found in elderly people who complain of a crampy feeling after meals when any exercise is indulged in. Even slow walking suffices to arouse the pain, which ceases as soon as the patients stand still or sit down. The peculiarities of this symptom are as follows: it affects only those who are advanced in years; it is most troublesome during the two or three hours which follow the ingestion of food; it is not accompanied by local tenderness, valvular lesions of the heart, or dyspnœa; the digestion is very slightly if at all impaired; it is a very obstinate symptom, resisting all methods of treatment and lasting for months and years. Arsenic, potassium iodide, and nitroglycerin are alike unavailing. It does not affect the general health, but remains as a very annoying symptom. Van Valzah and Nisbet ascribe this symptom to the gastric localization of arteriosclerosis, and liken it to the ordinary muscle-cramps of this condition.—*Cleveland Journal of Medicine.*

Unusual Dosage of Diphtheria Antitoxin.—H. L. Nietert reports the case of a young woman of twenty-one years, suffering from diphtheria, to whom 25,500 units of antitoxin were given without any ill effects. The serum was ineffective, probably because there was streptococcus infection in addition to the diphtheria infection. An abscess of the jaw was found to contain the diphtheria bacillus. The patient's septic condition finally yielded to venesection and transfusion of saline solution and recovery was uneventful.—*St. Louis Medical Review.*

New York, July 27, 1901.

KOCH'S ALLEGED DISCOVERY.

THE cable reports that Professor Koch, of Berlin, has presented a communication to the British Congress of Tuberculosis, asserting the absolute non-identity of human and bovine tuberculosis. He asserts, it is reported, that he has been unable to induce tuberculosis in animals by inoculation with human tubercle bacilli, and concludes from that that animal tuberculosis is not communicable to man. The most important deduction from this fact, if it were a fact, would be that there was no danger to man from tuberculous cattle, and that the feeding of milk from such diseased animals to babies would be harmless. It is a pity that Koch's true standing as a scientist is not so well appreciated by the public as it is by the medical world, for with the belief in his authority still extant among the laity, the publication of these views may do infinite harm. How great this harm may be, if Koch is wrong, can be judged by the headlines in *The Herald*, announcing the alleged discovery: "Professor Koch's New Discovery—Bovine Tuberculosis not Transmissible to Man, and Very General Fear Unfounded—No Harm to Use Milk or Meat—Diet from Infected Cattle, German Bacteriologist Holds, Can be Consumed with Impunity."

Of course, we cannot discuss Koch's paper from the imperfect abstracts of it cabled to this country, but we are justified in two comments upon it. In the first place, Robert Koch is not the authority he gave promise of being earlier in his career, and there is no longer reason to accept as true any assertion which he may choose to make, simply because he has made it. The keen striving after exactness of the scientist has been dulled in him more or less, as was shown in the matter of tuberculin and of T. R., and in that of his assertions regarding malaria. He has lost the caution of the real scientist and has put on the assumption (the cocksuredness, we are tempted to say) of the poseur. He asserts with positiveness what men like Adami and Theobald Smith suggest with caution.

And this leads us to the second remark we have to make on this publication. This alleged discovery of Koch is not original with him, any more than was that of the agency of the tick in the spread of Texas fever. He was preceded in the latter by Theobald Smith, and he is preceded in the former by the same investigator. In 1898 Smith presented a communication to the Association of American Physicians, in which he detailed a number of experiments showing marked differences between the bacilli of bovine and those of human tuberculosis. These differences were morphological, cultural, and in the results of inoculation, and were sufficient to warrant the belief that the two diseases were distinct, though possibly allied affections. Sputum bacilli, he said, cannot gain lodgment in cattle through the ordinary channels, but, owing to the impossibility of making inoculation experiments in the reverse order, from cattle to man, the question of the transmission of bovine bacilli to the human must, for the present, remain undetermined. However, influenced apparently by the few seemingly indubitable instances of the transmission of tuberculosis from animals to man, he expressed the opinion that "the occasional entrance of bovine bacilli into the human body might open the way for the introduction of a virus of a higher level." Adami, also, while not denying the possibility, and, indeed, arguing that it should be accepted for prudential reasons, yet admits that the evidence of direct transmission from animals to man "is singularly slight." Others, among whom are Frank S. Billings and Edward Moore—two acute observers who have enjoyed exceptional facilities for the study of bovine tuberculosis—deny that man is susceptible to this disease.

This question, from its very nature, is a difficult one to solve, but it is of the greatest importance, economical as well as nosological, and it must be determined absolutely within a very short time. If the assertion of Koch shall have the effect of shaking the firm belief to the contrary, which is now held by the vast majority of the medical profession, and of spurring on to greater efforts and more searching investigation the few who are at present studying the subject, it will have served a useful purpose. But it is unfortunate that he should have communicated it prematurely to reporters of the secular press, and so gained the wide audience of an impressionable laity before he presented it to the scientific body to which he was accredited. It was unprofessional and may be productive of incalculable harm.

THE NATURE AND THE TREATMENT OF PERNICIOUS ANÆMIA.

IT cannot be said that a satisfactory answer has yet been given to the question as to whether so-called progressive pernicious anæmia is a protopathic or a deuteropathic disorder. While often no underlying cause can be discovered, at times the characteristic symptoms and blood-changes are observed in connection with definite etiological factors, such as intestinal parasites, atrophy of the gastric tubules, etc. It is now pretty generally believed that the disorder is dependent essentially upon excessive blood-destruction, with deficient blood-regeneration, but the influence or influences responsible for these changes are as yet not known. It has even been suggested that the affection is of infective origin, and in this connection the opinion of Wm. Hunter that the infection may be derived from the alimentary tract is worthy of serious consideration.

A good deal of study has been devoted to the number and the characteristics of the blood-corpuscles and to the percentage of hæmoglobin in cases of pernicious anæmia and comparatively little to the chemistry of the blood. It has, however, been noted that the dry residue of the blood is greatly reduced, about one-half, and that the amount of water present is distinctly increased, while an excessive amount of iron has been found in various internal organs, such as the spleen, the bone-marrow, the lymphatic glands, and espe-

cially the liver. Th. Rumpf (*Berliner Klinische Wochenschrift*, No. 18, 1901) has observed, in addition, that the blood is rich in chlorine and deficient in potassium, iron, and fat. It was found further that the amount of water in the substance of the heart in a fresh state exceeded, while that in the liver, the spleen, and the brain was less than the normal. The dry residue of the heart, the liver, and the spleen was considerable, while the blood, the heart, liver, spleen, and brain contained minimal amounts of fat, and the amount of sodium chloride in the heart, the liver, the spleen, and the brain was large. The amount of potassium was above the average only in the liver, but less in the remaining organs. The amount of iron in the liver and the spleen was much greater than normal.

It is pointed out that if pernicious anæmia is dependent upon excessive hæmolysis and insufficient hæmogenesis, and if the former is due to the development of toxic substances, it is possible that these are in some way related to the potassium present in the blood-corpuscles, the withdrawal of which must be looked upon as a cause of the blood-disintegration. A similar withdrawal or interference with the assimilation of potassium may take place elsewhere. Accordingly the administration of potassium-salts in readily assimilable form constitutes a rational therapeutic procedure. It is true the pill of Blaud, containing potassium carbonate and ferrous sulphate, has long been employed in the treatment of anæmic states, but by this means a combination—potassium sulphate—is formed that is rapidly eliminated. Rumpf, however, has for a number of years administered potassium carbonate, potassium tartrate, or potassium citrate in doses of from 7½ to 10 grains under such conditions, in conjunction with an active preparation of iron, with most satisfactory results.

ANTI-TYPHOID INOCULATION.

Inasmuch as typhoid fever is a self-limited disease, and one attack affords relative protection from subsequent attacks, there would seem to be ground for the hope that immunity may be conferred by preliminary treatment with typhoid-bacilli or their products. The reports as to the results of such measures, particularly in the case of British soldiers sent to South Africa, are as yet somewhat conflicting, although the good effects appear to be predominant. According to a recent statement by Dr. A. E. Wright (*British Medical Journal*, May 4, 1901), based upon statistics furnished by Col. W. J. Fawcett, principal medical officer in Egypt, there were, during the year 1900, among an average annual strength of 2,669 uninoculated British troops in Egypt and Cyprus, 68 cases (2.5 per cent.) of typhoid fever, with ten deaths (0.4 per cent.); and among an annual average strength of 720 inoculated troops, but one case (0.14 per cent.) of typhoid fever, and this terminated fatally. Colonel Fawcett adds further that the figures do not fully disclose the measure of protection afforded by the inoculation, inasmuch as the number of uninoculated included soldiers inoculated in previous years; so that the number of uninoculated is really smaller, and that of inoculated actually larger than is apparent. On the other hand, the number of cases and of deaths in both sets of troops is entirely accurate, none of those inoculated in previous years having contracted typhoid fever. Further, in the single and fatal case occurring in the inoculated, the disease developed on the twenty-third day after inoculation, therefore before sufficient time had elapsed for protection to have been established.

STRONG DRINK AND CRIME IN THE GERMAN ARMY.

The misguided creatures who, through their action in abolishing the army canteen, have driven hundreds of our soldiers to drunkenness might pause a while in their hour of exultation and study some statistics cited by a writer in a recent issue of the *Kreuz Zeitung* of Berlin. According to this showing, in 120 army prisons throughout Germany forty-six per cent. of all the murderers committed their crimes while under the influence of drink. Sixty-three per cent. of the cases of manslaughter, seventy-four per cent. of serious injury to the person, and seventy-seven per cent. of criminal immorality are due to the same cause. In the navy, out of 1,671 punishable cases during the last six years, seventy-five per cent. of the most serious cases have been due to drunkenness.

This overmastery by strong drink comes not from the use of beer and light wine, such as was formerly obtainable in the "post exchange" in our army but from indulgence in "schnapps." This is the German equivalent of the whiskey served to our soldiers in the hundreds of dram shops which form a cordon around the army posts, and which were established there as a direct and logical result of the action of Congress influenced by the W. C. T. U. and other well-meaning, but sometimes pernicious, organizations.

News of the Week.

Unseasonable Diseases.—Smallpox, which is usually regarded as a winter disease, has prevailed to a greater extent in this city since the mild weather began than during the winter. During May and June there were over eight hundred cases, while from the middle of December to April 30, there were less than seven hundred cases reported to the Health Department. Owing to this rapid increase, with which the Health Department is evidently unable to cope, the Board of Estimate has authorized a bond issue of $65,000 in the hope that with this amount more can be done in vaccinating the well and isolating the sick. Another disease which is distinctly one of the colder season, especially of early spring, is pneumonia. But there have been many cases of that affection in New York during the past month, the various hospital records showing an unusual number of cases even now under treatment.

The Ontario Medical Association, at its recent annual meeting at Toronto, elected the following officers for the ensuing year: *President*, Dr. N. A. Powell, of Toronto; *Vice-Presidents*, Drs. R. Ferguson, of London, R. W. Garrett, of Kingston, L. C. Prevost, of Ottawa, and J. L. Turnbull, of Clinton; *General Secretary*, Dr. H. C. Parsons, of Toronto; *Assistant Secretary*, Dr. George Elliott, of Toronto; *Treasurer*, Dr. A. R. Gordon, of Toronto.

Mosquitos are more than ordinarily numerous this season in certain parts of New York and of the resorts in its neighborhood, and the opportunities for waging a crusade against them according to modern methods are ample. Prof. John B. Smith, the New Jersey State Entmologist, is credited with the statement that many mosquitos in that State

breed in running water instead of stagnant pools, and if that is the case it is difficult to see how their eggs and larvæ can be destroyed except by increasing the number of their natural enemies, such as the sunfish and dragon flies. The first skirmish against them is reported to have resulted in a victory for the mosquitos in South Orange. A determined effort has been made by the Village Improvement Society there to reduce the number of those pestiferous insects by oiling the surface of all bodies of standing water, but hitherto the results have been unappreciable. It is said that it is impossible to gain the cordial co-operation of all the citizens of the place, and the men who refuse to oil their own waste waters breed mosquitos enough to supply the entire village. Some of these opponents of progress, in order to enlist the support of the people at large, have invented and telegraphed to the New York papers an ingenious tale which seems to have obtained credence among many of the simple Jerseymen. They say that another danger has been added to country life since the oil was spread upon the mosquito-troubled waters of South Orange. The mosquitos absorb quantities of the oil, and when they gain entrance to a house, the occupants have to be very vigilant lest the insects fly into a lamp or gas jet and catch fire! These veracious scientists affirm that this has happened on more than one occasion, and the blazing mosquitos have set fire to curtains and draperies before the insects were consumed. In New Orleans, much is hoped from the plan of sprinkling the streets with oil instead of water. The object of this is primarily to lay the dust, but as the ever-present mosquitos in that city are supposed to lay their eggs in the drains, it is thought the oil escaping into them will have a depressing effect on the larvæ.

Beer vs. Water.—It is said that Dr. Tanner, of fasting fame, now sixty-eight years old, has challenged the brewers of Denver to a fasting contest. Six men are to drink beer only and he is to drink water. The brewers have agreed to the contest.

Colorado State Medical Society.—At the thirty-first annual meeting of this society, the following officers were elected: *President*, Dr. R. W. Corwin, Pueblo; *First Vice-President*, Dr. W. W. Grant, Denver; *Second Vice-President*, Dr. P. J. McHugh, Fort Collins; *Third Vice-President*, Dr. L. J. Forhan, Trinidad; *Corresponding Secretary*, Dr. J. M. Blaine, Denver; *Recording Secretary*, Dr. Minnie C. T. Love, Denver; *Assistant Recording Secretary*, Dr. J. T. Melvin, Saguache; *Treasurer*, Dr. William J. Rothwell, Denver. *Board of Trustees*, Drs. Hubert Work, Pueblo; S. E. Solly, Colorado Springs; J. T. Eskridge, A. Stedman, W. E. Wilson, E. J. A. Rogers, and J. N. Hall, Denver.

Northwestern University Medical School.—N. S. Davis, Jr., has been elected Dean, and Arthur R. Edwards Secretary, of the Faculty of this school, otherwise known as the Chicago Medical College. Wesley Hospital, in close connection with the College, has been informally opened to the profession, and after complete equipment the formal opening will take place. The hospital will accommodate three hundred patients. Plans are completed and the money is raised for an amphitheatre and operating rooms at Mercy Hospital, with a seating capacity of four hundred. Drs. C. L. Mix and P. T. Burns have been appointed Assistant Professors of Anatomy.

The Havana Health Report.—The report of Major Gorgas, Chief Sanitary Officer of Havana, for the month of June, states that there were no cases of yellow fever in that city during the month, this being the first June since 1761 which has been free from the disease. The last death from yellow fever occurred on March 16. Since the middle of February, the whole management of yellow fever has been based upon the supposition that the mosquito is the medium of its transmission from person to person, the theory originally brought forward and elaborated by Dr. Charles Finlay of Havana, and finally entirely established by the beautiful and complete experiments of the Yellow Fever Comission, of which Major Walter Reed was President. When the results of these experiments were made known, the Military Governor, General Leonard Wood, directed that every effort be made to carry out disinfection on the lines indicated by this discovery, and the result of four months' work has been to strengthen the conclusions reached by the Board. During the past three months yellow fever was introduced into Havana from without three separate times, but each time the disease was recognized, and its spread prevented. Soon, if this remarkable state of affairs continues, Havana will turn the tables on the rest of the world and quarantine against New York and other sources of infection. Indeed, Major Gorgas seriously proposes this measure in the case of smallpox. There has been no case of that disease in Havana since July, 1900, but prior to the American occupation this was one of the principal causes of death in Havana and all reasonable precaution should be taken to keep it out. With smallpox so general in New York and New Orleans, every person coming into Havana from these points is a possible conveyor of the disease, and Major Gorgas therefore has requested the Governor General to require all passengers from these points to show evidence of immunity either by successful vaccination or having previously suffered from the disease before they are permitted to land on the island.

The Streets of New York are getting very dirty again, as one cannot fail to observe who has occasion to traverse those lying at any distance east or west of the main arteries of travel, or even Fifth Avenue. Recently a number of physicians and other residents on the east side presented a very strongly worded protest to the Commissioner of Street Cleaning against the neglect of the department in disposing of garbage during the hot weather. It is little short of infanticide to neglect the cleaning of the streets in summer in the tenement-house districts—and the cry of the innocents is one that even a political office holder cannot afford to disregard.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical corps of the Navy for week ending July 20, 1901: July 17—Asst. Surgeon F. M. Bogan, detached from the Scorpion when put out of commission, and ordered to the Machias. P. A. Surgeon C. P. Bagg, detached from the Culgoa and ordered to the Yorktown. July 18—Surgeon C. J. Decker, detached from the Newark, when put out of commission, and ordered home to wait orders. Asst. Surgeon W. H. Bucher, detached from the Naval Hospital, Norfolk, Va., and ordered to the Dixie. July 22. Asst. Surgeon P. E. McDonnold, ordered to duty at the Naval Museum of Hygiene Washington, D. C. July 25

The New Jersey State Dental Society held its thirty-first annual meeting last week at Asbury Park under the presidency of Dr. F. E. Isall Riley, of Newark. The election of officers resulted as follows: *President*, W. M. Fish, of Newark; *Vice-President*, Frank Hindle, of New Brunswick; *Secretary*, Charles A. Meeker, of Newark; *Treasurer*, Henry A. Hull, of New Brunswick. The association will meet again in Asbury Park next year.

Camp for Tuberculous Patients.—The officers of the Free Hospital for Poor Tuberculosis Patients at Philadelphia, who have in view the erection of buildings at White Haven, Pa., have arranged to establish immediately a camp on the 215 acres of high land purchased recently as a site. The privileges of the camp will be available only to male patients strong enough to rough it a little, and not requiring special medical attention. The camp will, however, be visited periodically by a physician from Philadelphia, while the services of a local physician will be available for any emergency.

The Plague.—Mail advices from the East bring news of a steady increase in the number of deaths from plague in Hong Kong, and report that the percentage of Europeans who have succumbed to the disease is much higher than on any occasion of former epidemics. The latest advices recorded the mortality in Hong Kong from plague at forty-five deaths every twenty-four hours, and the number of new cases at fifty a day. This disease appeared again at Oporto, the latter part of June. The Orient Line steamship, *Ormuz*, from Sydney for London, landed at Plymouth, July 22, two persons, supposed to be suffering from bubonic plague. One case developed after the ship had left Marseilles. A sailor on the steamship *Hohenfels*, which arrived at this port from Calcutta a few days ago, was detained at quarantine because of a suspicious illness accompanied by a glandular enlargement of the groin, and a bacteriological examination proved the case to be one of plague.

Danger in Incandescent Lamps.—At an inquest held recently in Providence, R. I., it was learned that death had resulted from touching an incandescent lamp which seemed to be out of order. Experts testified that in small towns where the current was sent through a small wire the house-converter might become deranged, when the wires would receive the entire 2,000-volt current, instead of the 104 volts intended for the house. This is said not to be possible in the larger cities, where a current of low voltage is distributed by means of copper cables, and a converter is not necessary.

Trouble at the New Jersey State Hospital.—The employees at the State Hospital at Trenton have signed a public protest against the food supplied to them and the patients in that institution. They complain that they receive nothing but canned meats and vegetables, and that it is impossible for them or the patients to obtain proper nourishment. One of the Board of Managers asserts that the complaints are ill-founded, and that the trouble arises from the want of harmony between the conflicting medical and political authorities of the hospital.

Inspecting Proposed Sites for the State Hospital for Consumptives. Governor Odell and the commissioners were in the Adirondacks last week inspecting the Lake Clear, Raybrook, and Dannamora sites for the tuberculosis hospital. It is expected that a decision respecting the best location will soon be arrived at.

Dr. Edward S. Brush has been nominated by the Republican party for Mayor of Mount Vernon, N. Y., Dr. Brush was the first mayor the city of Mount Vernon ever had. He was elected in 1892, and there has been a general demand for his renomination ever since, but he has always declined.

Complaints Against a Tunnel.—District Attorney Philbin went before the Grand Jury of this county a few days ago, and presented a complaint against the New York Central Railway tunnel, beneath upper Park Avenue. He requested the Grand Jury, if it found the facts in the complaints sufficient, to make a thorough investigation. A number of residents in the neighborhood of the tunnel have complained that the gases and vapors that arise from the tunnel are a menace to health and constitute a public nuisance, and others who are obliged to pass through the tunnel daily in the cars of the company have complained that the asphyxiating gases cause not only discomfort but veritable injury to health. Should the Grand Jury decide that the tunnel is conducted in such a way as to constitute a public nuisance, indictments will be found against the company.

A Death Under Ether occurred one day last week at the Manhattan Eye and Ear Hospital in this city. The death was that of a child, three years old, who was undergoing a second operation for strabismus. The first operation had been performed early in June, and there had been no untoward symptoms while the child was under the anæsthetic at that time.

Another Swindle in Brooklyn.—The Borough of Brooklyn has afforded of late a more or less profitable field for the operations of various individuals and gangs of swindlers. The latest to come to the public notice is an impersonator of Dr. Ray, the physician in charge of the smallpox hospital on North Brothers Island. The man goes to the families of smallpox patients whose names he gets by reading the news papers, and representing himself as the physician in charge or his representative, tells them that he can get better treatment for their friends and relatives if they will pay him. In this way he is said to have fleeced a number of the citizens of Brooklyn.

Florida Yields Jurisdiction of Quarantine.—The State of Florida has yielded to the Federal Government its jurisdiction in quarantine matters. Three quarantine stations now controlled by the State will be released to the Treasury Department, and officers of the Marine Hospital Service will be placed in charge.

The Onondaga County Medical Association was organized on Thursday evening, July 18th, at the house of Dr. Henry D. Didama, of Syracuse. By-laws were adopted, and the following officers were elected to serve until the annual meeting, which will be held on the third Monday in February: *President*, Henry D. Didama; *Vice-President*, Adelbert D. Head; *Secretary*, Bernard S. Moore; *Treasurer*, Alexander J. Campbell; *Member of the Executive Committee*, Amos S. Edwards; *Fellow*, Wm. J. Ayling; *Alternate Fellow*, Charles B. Gay, all of Syracuse. The next meeting of the Association will be held on the third Monday in August, the place to be decided by the Executive Committee.

The British Congress on Tuberculosis was opened on Monday of this week in St. James' Hall, London, by the Duke of Cambridge in behalf of the King. Lord Lansdowne, in a brief address, welcomed the foreign delegates in behalf of the British Government, and Lord Lister followed with a welcome on the part of the medical profession of the United Kingdom. A telegram of greeting from King Edward was read, and just before the adjournment of the session the Duke of Cambridge announced that a gift of £120,000 ($600,000) would be forthcoming for the purpose of establishing the first public tuberculosis sanatorium as soon as the recommendations of the congress concerning its establishment had been formulated. On Tuesday, Professor Koch, of Berlin, read a paper in which he

announced his conviction that bovine and human tuberculosis were two distinct diseases. He also expressed his adherence to the now nearly universal belief that tuberculosis is not inheritable. The chief source of contagion, he thought, was through the sputum, and he spoke in complimentary terms of the work in restricting the disease done by the New York City Health Department under the direction of Dr. Herman M. Biggs. He said there was reason to hope for the ultimate extinction of tuberculosis. On Wednesday, a paper was read by Professor Brouardel, of Paris, in which he dissented from the views of Koch regarding the non-communicability of bovine toberculosis to man. The main reliance in the prevention of the disease lay in hygiene, he said, and too much praise could not be given to those in America who were making such strenuous efforts to prevent spitting in public places; once this practice was abolished, tuberculosis would rapidly decrease. Dr. G. A. Heron, of London, read a paper on tuberculin which he regarded as an invaluable aid to diagnosis, and an almost certain remedy in the early stages of tuberculosis. On Thursday King Edward received the foreign delegates at Marlborough House.

The Stillman Infirmary is the name of a hospital for the benefit of members of Harvard University, recently erected on Mount Auburn Street by Mr. Stillman, president of the National City Bank of New York. The infirmary contains private rooms and wards, a kitchen, a laundry, a dining hall for servants, nurses' quarters, and other accommodations. The building is of red brick and limestone.

Objections to Peripatetic Sunbathers.—The inhabitants of a village on Long Island are up in arms against the proprietor of a local sanatorium, who has advanced views of the healing powers of air and sunlight. His patients, it is alleged, go about the village and surrounding country clad only in bathing suits or less, and those among whom they go object that the costume is too light even for summer wear, and they insist that that particular therapeutic method is one that should be carried out in the seclusion of the sanatorium grounds.

A Maternity Hospital at San Juan.—The Women's Aid Society of Porto Rico has issued an appeal for funds to establish a maternity hospital at San Juan. The municipal authorities there have given a site, but only $6,000 has been raised toward the erection of a building. The need for a lying-in hospital is so great, however, that the building committee have decided to go to work and erect the structures that are absolutely necessary, hoping to complete the entire hospital at no distant day. The first building will consist of a maternity ward, a nursery, bathroom, dispensary, and administration offices.

A Divine Healer Out of a Job.—Francis Schlatter, who enjoyed some notoriety a few years ago in the West and drew large crowds by reason of his powers of "healing," has come to grief in Washington, where he was recently committed to the workhouse for thirty days for vagrancy.

The Harvard Medical School, three of the five buildings of which will be erected by Mr. J. Pierpont Morgan of this city, will be located in Brookline. It will cover twenty-six acres of land, part of which will probably be used for a dental college and a hospital. The buildings will cost at least $2,000,000, and will bound three sides of a courtyard.

Politics and Charities.—Miss Julia C. Lathrop, of the Illinois State Board of Charities has resigned from that body, because of the election of a politician to the office of secretary. In a letter to Governor Gates explaining her action she says that the new secretary represents all the standards and conditions of the previous administration, which a spasmodic attempt had been made to correct, and that his election is tantamount to a public declaration that politics will have full power to interfere with the management of the State institutions.

The Smoke Nuisance.—Even in the worst of sultry humid days and nights there are lawbreakers who persist in polluting the air with the murk and the reek of big black clouds of foul smoke from soft coal. These sooty and fuliginous offenders should be confined to cells. Fines don't scare them into mending their ways. Only imprisonment will teach them the lessons which they need. Pure air is so precious, especially in hot weather, that the owners of chimneys which belch out the vilest fumes and the inkiest of smut from furnaces stuffed with bituminous fuel should be arrested, arrainged, and put in jail.—*The Tribune.*

The Manufacture of Formaldehyde.—Some capitalists in Buffalo are promoting a scheme to establish a factory in that city to compete with German manufacturers in the making of formaldehyde.

Obituary Notes.—Dr. R. N. Cooley, of Hannibal Center, N. Y., died at his home in that place, on July 17, at the age of seventy years. He was a graduate of the Castleton (Vt.) Medical College in 1850, and was one of the oldest medical practitioners in Oswego County.

Dr. Samuel Caley, a homœopathic physician in Mount Holly, N. J., died suddenly of heart disease on July 17. He was a graduate of the Hahnemann Medical College of Philadelphia in 1878.

Dr. William H. Gobrecht died at his home in Washington, on July 19, at the age of 72 years. He had been an invalid for some time and his death was accelerated by the heat. He was a graduate in medicine of the University of Pennsylvania, and was for several years a demonstrator of anatomy there. He served during the war on the staff of Gen. Hancock. For ten years after the war he was a demonstrator of anatomy in the University of Ohio. He was author and editor of several works on anatomy and its practical applications.

Dr. George A. Blanchard died from typhoid fever, at Scranton, on July 10. He was Assistant Surgeon to the Thirteenth Pennsylvania Regiment and had served during the Spanish-American War. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1895.

Dr. J. R. Caldwell, late quarantine physician at the State Quarantine Station at Marcus Hook, Pa., died July 20. He served with distinction during the Civil War.

Dr. Lawrence Wolff died at Philadelphia, on July 21 at the age of fifty-six years. He was born in Ausbach, Bavaria, coming to this country at the age of fifteen years. He was graduated from Jefferson Medical College in 1880 and for eight or nine years was demonstrator of chemistry in that institution. He was for a time one of the visiting physicians to the German Hospital and also Clinical Professor of Medicine in the Woman's Medical College.

Dr. John F. Trenchard died at Fairton, Cumberland Co., Pa., on July 12, at the age of 81 years. He was a graduate of Jefferson Medical College, in the class of 1847. He had only recently retired from practice, in which he had been engaged for many years in Philadelphia.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 18, 1901.

Ovarian Cyst with Twisted Pedicle.—Charles L. Scudder reports the case of a fluctuating and tender tumor in the lower right abdomen of a woman of twenty-two years who had had a miscarriage a few months previously. The menses were regular, there were pain, slight fever, and slow abdominal enlargement. Operation showed a cyst of the right ovary, with its pedicle twisted twice to the right. Flakes of fibrin were found about the pedicle; the surface of the tumor was dark and rough in appearance. The cyst was removed and recovery was uninterrupted.

Advantages of Sanatorium Treatment of Pulmonary Tuberculosis.—Henri T. Fontaine considers that the hygienic dietetic treatment can be carried out much more thoroughly in closed resorts than in open ones or in private practice. There is constant supervision by the physician, who can prescribe the amount of exercise and rest necessary, and superintend food, toilet, ablutions, breathing exercises, and amusements. Great courage is gained in a sanatorium in regard to fresh air, both from the advice of the physician and the example of other patients. Rest can be combined with the fresh-air cure in a way impossible elsewhere. Expectoration and destruction of the sputum can be properly regulated, and all table utensils thoroughly steamed and scalded. The mental atmosphere also is good, for, contrary to the usual idea, the tone of such a place is cheerful, since every one is trying and expecting to get well, and symptoms which at home would cause alarm, are treated with levity or not discussed at all.

The Alleged Increase of Cancer in Massachusetts.—William F. Whitney says that if death from cancer should go on at the apparent geometrical rate of increase of the past fifty years, in two and a quarter centuries every person over thirty years would die from that disease. This rate, however, is probably only arithmetical and due to better diagnosis and registration, and until the ratio of deaths over thirty years has reached 8 to 9 per cent., which is shown by autopsies to be the true rate for cancer, it is not justifiable to speak of the increase as inherent in the disease itself. Comparison with other States and countries shows the rate for Massachusetts to be about the same as theirs, with greater variation between the males and females than is the case in Austria, which is remarkable for the correspondence between the two sexes. In the distribution in the New England States there is no geographical feature that explains the slight variation which is easily within the limits of better registration.

Medical News, July 20, 1901.

A Study of Sixteen Hundred and Fifty Blood Examinations for the Widal Reaction, with Special Reference to So-called Partial Reactions.—Robert J. Wilson bases his conclusions as to partial reactions on the hospital cases of which fairly accurate histories were kept. Less than seven per cent. of the partial reactions were found in typhoid infections. These reactions occurred with greater frequency in both tuberculosis and malaria than they did in typhoid. The writer concludes that these cases where the Widal reaction has been present are only further evidences of the already known practical value of the reaction; and that the so-called partial reactions are valueless so far as the clinician is concerned.

A New Method of Determining Approximately the Amount of Hydrochloric Acid in the Gastric Contents.—Max Einhorn describes this procedure as follows: A measured quantity of stomach contents is placed by means of a glass rod upon a strip of dimethylamidoazobenzol paper (one-half by eight centimeters). If the paper turns red one drop of the contents is diluted with two drops of water in a small porcelain dish. A glass rod is dipped into the mixture and the test paper again touched. If it still turns red, one or two more drops of water are added, and the procedure is repeated as before. This is done until only a slightly red or almost no red color is produced by the mixture upon the test paper. In this way the amount of dilution required for a trace reaction with the test paper is determined. It is clear that the more HCl there is in the stomach contents the more the latter can be diluted, still giving a trace reaction with the reagent and test-paper.

Local Treatment of Female Diseases, and Its Abuses.—A. L. Benhan believes that the most dangerous procedures are perhaps intra-uterine examinations, operations, and applications. The most dangerous instruments used in treating these diseases are dilators, sound, and curette. The sound should never be used. The curette is useful when the uterus has failed to expel part or the whole of the products of conception, or when later the uterus does not contract because of fungous granulations of the membrane of uterine cavity. The curette should be used with great circumspection and after a careful eliminating diagnosis. Its use should rank with major operations and similar careful preparation should be made for its performance. Large, smooth, loop curettes should be employed to remove placental débris. The employment of pessaries has been much abused. Electricity as usually applied seems futile. The principles of practice must recognize the causes involved in producing female diseases, such as constipation, the results of abnormal confinements, of repairs not made in season, and of sexual infections. Calomel and salines indirectly lessen pelvic engorgement. Hot-water douches in the recumbent posture, followed by soothing alkaline or stimulating astringent solutions of moderate strength, are useful, except in tubal and ovarian diseases, but if pain occurs when they are administered it is proof of harmfulness. Local treatment will seldom be required. The use of tampons of cotton or wool with glycerin are valuable, but should be used only when the patient is confined in bed. Great care should be used in this procedure. A torn cervix should be repaired by the Emmet method. Perineal laceration should be repaired by the American or Emmet method of elevating the perineum and anchoring it well up. The close study of many female diseases will limit the range of usefulness of "treatments," but enlarge the sphere of surgical relief and improve the care of remote and general disturbances.

Disinfection Within and Without the Body in Diphtheria.—M. A. Veeder calls attention to the fact that the Klebs-Loeffler bacillus can live perhaps from year to year in underground drains. When incapable of being flushed adequately these can be sterilized by the aid of chlorine gas. In the treatment of cases he holds a square of antiseptic gauze over his mouth and nostrils with the left hand while the right is free to use the tongue depressor or swab. Both hands and the face of the physician should be wet with the sublimate solution before and after the examination, and the gauze may be burned after being used. This, together with frequent spraying and cleansing of the mouth, throat, and nostrils, and bacteriological testing, affords very complete security against either giving or receiving infection. Lead pencils should be forbidden diphtheria patients, since they are apt to put them in the mouth. Teeth having cavities should be plugged with a pledget of cotton, saturated with some disinfectant solution, before and after meals. The mouth and nostrils should be constantly sterilized as far as possible. Peroxide of hydrogen made alkaline by lime-water or by equal parts of Dobell's solution, is very good. Chlorine water, with a little tincture of iron, is very efficient. A soft camel's hair toothbrush, kept in a two per cent. solution of carbolic acid, and used with a lather of castile soap, is of great service; dental floss used between the teeth assists in keeping them clean also. These measures should be persisted in until the mouth is perfectly normal again.

Static Electricity in the Treatment of Sprain.—Leonard C. Stanford describes this treatment. The electricity is generated from a large Holtz machine. The patient is placed on an insulated platform, which is connected with the negative pole of the machine by a brass rod. An electrode, connected with the positive pole by a brass chain, gives off the spark after the circuit has been completed, the length of the spark is from two to four inches. The application is made over and around the painful areas by the positive electrode. It lasts from ten to fifteen minutes, occasionally broken by a short intermission. For sprains with little or no effusion this treatment is very satisfactory. When effusion is present there seems to be little effect besides relief of the pain. Injuries of long standing are not generally so favorably influenced as those of the acute variety. Care in the administration of this treatment should be exercised, as occasionally an unpleasant reaction follows.

New York Medical Journal, July 20, 1901.

Common Law Rights and the Physician's Prescription.—J. W. Jervey's views are expressed in the following propositions: 1. The patient has no legal nor other right to demand a written prescription or written directions from the physician. 2. It is right and wise that the druggist demand and procure from the physician his written orders for the compounding of prescriptions. 3. The physician has the undoubted right to designate what pharmacist shall fill his prescription. 4. The written prescription is simply an order from physician to pharmacist. It is, through courtesy, and by virtue of custom and convenience, handed to the patient for transmission; but the latter has not, at any time, the slightest right of possession in the instrument. 5. The druggist has at least the right

of permanent guardianship (perhaps of outright possession) of the prescription, and he must keep it on file for reference and for any form of proper investigation. 6. There can be no right, extenuation, or excuse for a copy of a prescription, with physician's name attached, to be taken by druggist, patient, or any one else, without the authority of the physician. 7. The careful physician should invariably retain a carbon-paper facsimile copy of every prescription he writes. 8. The druggist has a legal right to utilize any formula that is uncopyrighted that may fall into his hands but he cannot, unauthorized, use the name of its author in connection with it. In most States, however, statutes would bar his selling intoxicants or other poisons except by direct order of a physician. 9. If a druggist refills a prescription without the order of the physician who wrote it, he does so on his own responsibility, and he has no legal or moral right to leave or place the physician's name on the container.

A Case of Traumatic Rupture of the Intestine.—F. T. Wright reports the case of a man of fifty-seven years who had, two hours before being seen by the physician, fallen into a hole by the side of a railroad track, and in falling had struck his abdomen against the end of a platform. Immediate examination revealed only evidences of general abdominal contusions and soreness. There was a left-sided, incomplete inguinal hernia, easily reducible, which gave no special symptoms. The next morning the condition was about the same, though the abdomen was somewhat more rigid. He went along for two or three days without much change, but on the fourth day a change of symptoms suggested that there was some bowel obstruction. The patient was apathetic, with a temperature of 97° and pulse of 96. The abdomen was excessively distended, and there was marked tympany. Pain was only moderate, but there was considerable tenderness on palpation on the left side just below the umbilicus. The abdomen was opened, and a bad condition of general peritonitis found. A search among the coils of gut revealed a longitudinal rent one-third of an inch long, situated about two feet above the cæcum, on the aspect of the bowel opposite the mesentery. The patient succumbed before the operation was completed. The author suggests that the case illustrates the need of carefully inquiring into the nature of the injury in these abdominal cases, the advisability of carefully watching the leucocyte count (which was done in this case), the extreme degree of peritonitis which may accompany very mild general symptoms, the necessity of early diagnosis and prompt intervention, and lastly, the difficulty of making a diagnosis, as to etiology, in cases of obstruction.

Journal of the American Medical Association, July 20, 1901.

Types of Membranous Pharyngitis.—W. E. Casselberry calls attention to the different micro-organisms capable of giving rise to deposits of false membrane upon the pharyngeal mucosa and to the necessity of a bacteriological diagnosis if one would arrive at positive conclusions as to the nature of a given case.

Œdematous Laryngitis.—J. S. Gibb makes the following division of cases: 1. Those in which there is no true inflammatory condition, but simply a transudation of serum into the submucous tissues. These cases are seen in affections of the kidneys, liver, and heart. 2. Acute catarrhal cases seen in a mild degree in all forms of acute catarrhal laryngitis. These are transient and pass away with the exciting cause. 3. Secondary septic processes complicating the zymotic diseases. Here we may have a temporary œdema or a prolonged condition leading to abscess formation. 4. Cases in which the infection occurs immediately from some source in the pharynx or larynx. These are sometimes called acute infectious œdema. The history of these is essentially one of sepsis. The initial influenzal or catarrhal attack may not be severe. The local inflammatory condition and accompanying dyspnœa are rapidly followed by pulmonary and general infection and sepsis. The majority perhaps of these cases as observed in recent years are due to influenza.

The Relation of the Middle Turbinate Body to Chronic Nasal Disease.—L. H. Baker calls attention to the fact that a portion of the middle turbinate should be removed whenever its retention leads to imperfect drainage from the accessory sinuses, or when we need to secure free access to the soil from which nasal polyps spring. The same operation may be indicated for the relief of fetid crusting of discharges on the upper portion of the nasal chambers in non-specific cases, or for the removal of the so-called "bullous hypertrophy" of the turbinate itself. Again, removal is indicated when the bone impinges on the sensitive areas of the septum and causes various nervous disturbances such as sneezing, coughing, asthma, headache, vertigo, even chorea and epilepsy. Finally, vasomotor rhinitis is often relieved by removal of the tip of the turbinate body. The author operates under cocaine and adrenalin, using Holmes' scissors and a snare. Packing with iodoform gauze is kept up for a day or two and is then discontinued. For home use, borax solutions are advocated, and insufflations of a lead iodide compound.

The Treatment of Laryngitis.—O. T. Freer says that all local remedies can be used by spray better than by other means. Protargol and the astringents are preferable when there is a decided amount of purulent secretion. The author has not obtained as good results with remedies of the thymol, eucalyptol and menthol group as with astringents. For acute submucous laryngitis, cold applications externally afford great relief. For laryngitis sicca we may use the protargol class of remedies, but they must be applied through a long spray tube, in fact we must treat the trachea as well as the larynx. For the hemorrhagic variety, tannic acid is recommended. In chronic laryngitis, the first thing to do is to cleanse thoroughly the parts and then to remove all causes of irritation which exist in the passage higher up. Alcohol should be given up and rest for the voice is often necessary. Every effort should be made to bring the general physical condition up to par. In the milder cases weak metallic solutions are of service. Ichthyol is recommended for laryngitis sicca. It is a non-irritating antiseptic causing contraction of vessels and paling of inflammed tissues.

Simple Gingivitis, Its Etiology and Treatment.—G. T. Carpenter says that among the local causes are irregularities and mal-occlusion, imperfect contour or loss thereof, improper use of the teeth causing lack of tone to the gum, inorganic substances used as tooth powders causing unnatural or insoluble deposits under the gum margins, with irritation, injudicious use of toothpicks, floss, rubber bands, etc. Constitutional causes include all cachexias and improper nourishment. Treatment may be laid down in the following propositions: Correct all mal-occlusions and restore perfect contour to crowns. Remove all local irritants and deposits, and make a light application of tincture of iodine to the affected parts and give instructions to prevent irritation and abuse of the gums; change the diet from mashed vegetables of all descriptions or soaked or cooked in milk to that of dry or Swedish toast, or whole wheat, to be ground thoroughly fine with the teeth, incorporated with the saliva and swallowed. This treatment should be followed, especially with children suffering from gingivitis. Corn meal makes an excellent dentifrice.

The Tongue as a Breeding Place for Bacteria.—H. M. Fletcher calls attention to the fact that of the seven nutrient media for bacteria in the oral cavity as mentioned by Miller, five are always present on a coated tongue, namely, normal saliva, buccal mucus, dead epithelium particles of food and exudations from diseased gums. Hence any lack of oral hygiene at once leads to excessive germ growth in the mouth. Such systematic disorders as tend to produce fever have their effect upon the mucous membrane, among the first of which is the "dry stage." In this stage the mucus is thicker, less abundant and dries quicker. This is as true of the dorsum of the tongue as of any other mucous membrane, hence the coating is usually pronounced and well formed by the time the physician is called to see the patient. The mucus which cements the layer of sordes upon the tongue and lips is not soluble in water, ether, alcohol, chloroform, or dilute mineral acids, but is soluble in alkaline solutions, and since nearly all of our food is either acid or neutral, and not one in a thousand thinks of scrubbing the tongue as a matter of cleanliness and protection, it certainly is a source of danger and infection, and an undoubted condition for perpetuating disease, especially with invalids. In order to test the solubility of mucus in alkaline solutions, try scrubbing the tongue with a tooth-brush filled with powdered biborate or bicarbonate of sodium, and notice how the coat disappears. Biborate is the least disagreeable. Protrude the tongue and scrub it from back to front until the coating is removed. When the tongue is to be examined for diagnostic purposes this should be done so that the real color and condition of the tongue can be examined. Then the diagnostic features will be misleading and of undoubted value. The use of the brush is much better than to scrape the tongue with a hard instrument.

The Gynecological and Obstetrical Significance of Girlhood.—H. P. Newman finds in the forcing period of modern educational methods an explanation of much of the trouble that threatens the maternal functions of the girls of to-day. The disturbance of the process of development of the generative organs, which is the chief concern of Nature in the pubertal period, the forced activity of other organs through misdirected or ill-timed educational methods result in a thwarting of the growth in the pelvic regions, and a condition there which is pathognomonic. In gynecological parlance we speak of it as infantile uterus.

r the puerile or juvenile cervix according to the degree of arrest of development. This typical maldevelopment of the cervix plays a disastrous rôle in the future history of the woman. Pain itself, not always pronounced in the beginning, gradually becomes a feature of the moment. Recurring monthly, this influence is baneful and like all chronic suffering, exhausting and devitalizing. The congestion incident to this state of things becomes more persistent as time goes on, until a passive congested state is continuous throughout the intermenstrual period. There is general lowered vitality and less resisting power, so that even should pronounced infection with inflammatory exudate be wanting, a low form of white-cell proliferation occurs, and the newly-formed connective tissue hardens, contracts, and, by constricting the lumen of the cervical canal, renders this important organ unfit to perform its functions. Out-door life should be rigidly insisted on for the girl as for the boy. The dress should be as free and unconfined as his. Forced mental development at the expense of the physical should be discouraged. In fact, due observance should be given to the hygiene and sleep, diet, dress and exercise. Pain should be relieved, not necessarily by drugs, but by sitz-baths, topical applications, heat, etc., or, if due to mechanical causes in the organs themselves, recourse should be had promptly to surgical intervention.

Philadelphia Medical Journal, July 20, 1901.

A New Method of Making Tannin Available as an Intestinal Astringent.—Albert C. Barnes and H. Hille have found that by the synthesis of nucleinic acid and albumin there results an entirely new body, which chemical analysis shows belongs to the nucleo-proteid class of bodies. Under certain conditions, this body enters into chemical combination with tannin and forms a yellowish-brown tasteless powder containing fifty per cent of tannic acid. This substance is insoluble, does not precipitate albumin, pepsin, or peptones. Experiment has proved that seventy-five per cent. of the tannin nucleo-proteid passes through the pylorus chemically unchanged, and it must be, therefore, practically free from astringent action upon the stomach. It has also been shown that this tannin nucleo-proteid but very gradually evolves tannin from its combination. Thus, as the remedy passes downward through the intestines, the astringent is brought into contact with the entire intestinal canal. The astringent action of tannin is more complete when but small quantities come in contact with any one part of the intestinal mucous membrane, while larger quantities produce local irritation. This new remedy should be successful in the treatment of diarrhœa and of various diseases of the intestines associated with diarrhœa. E. F.

Some Observations Respecting the Value of the Present Methods of Medical Education.—Augustus P. Clarke thinks that it is now imperatively demanded that there be established proper courses for medical students; courses that while duly fitting the student to enter upon the successful study of medicine, will admit of more expedition, be more conservative of his energies; courses that will have an alluring influence and that will lead the student along and beget in him the true spirit of scientific investigation, and, above all, afford the opportunity of allowing him to engage earlier in the more direct work to be carried on during his life. Many expedients have to be resorted to in the present methods, in order that the student may compass what is expected of him. The hobbies and pet theories of individual professors or instructors have to be studied or more or less considered—a partial comprehension of these may serve as a substitute for the real marks of scholarship. French, German, or other modern language should be acquired. Too much time should not be given to the ancient tongues. Four full years should be devoted to the study of medicine before the medical degree is given. Co-educational schools should be encouraged. Didactic courses cannot yet be dispensed with. Much original work should be done in examination and in the diagnosis of disease. The student should be able to write a good paper exemplifying a genuine scientific mode of observing facts and a ready and rational method of making a deduction. The student's standing, habits, and manner of pursuing work should be carefully observed by his instructors. His failures should bring to him kindly and wise criticism. The aim of the medical school should be to go and the student in all of the essential principles underlying the healing art, for the expertness of the specialist can be gained only by much post-graduate work, and by frequent contact with experts of the individual line to be pursued.

American Medicine, July 20, 1901.

On the Evils Arising from the Failure to Recognize the True Nature of Neurasthenia and Some Causes of This Failure.—W. W. Johnston gives a brief sketch of Darwin's life after the age of twenty-two. He shows the serious evils which follow the neglect to insist upon an entire abandonment of all work in the earlier stages of neurasthenia. No matter how serious are the symptoms presented in a case of neurasthenia, cure is the usual result if the treatment is radical enough and continued for a sufficient length of time. However, some cases are not curable by any mode of treatment. Incurability does not belong to the early stages of the disease, but to the later periods when the disease has continued for years without proper treatment. Patients themselves are often unwilling to admit the true nature of the disease. Again, there is a general want of appreciation of the symptoms of this disease among young physicians. More exact instruction in the diagnosis and treatment of neurasthenia should be given. There should be special institutions, sanatoriums, properly constructed and equipped with every device to secure rest, quiet, and seclusion, for the treatment of this disease. Forms of mental disturbance should not be treated under the same roof. The institutions should be for neurasthenics only, and ought to be managed by men specially trained for this work.

The Lancet, July 13, 1901.

A Case of Renal Colic with Unusual Symptoms.—C. Corben and J. Cropper report the case of a married woman of thirty years, who on the occurrence of renal colic presented many of the symtoms of appendicitis. In subsequent attacks the pain radiated upwards and backwards over the right scapula, and there was a good deal of catching of the breath as in pleurisy. Later cough and hæmoptysis appeared. The passage of several fragments of urate calculus cleared up all the symptoms.

A Case of Meningitis, Probably Influenzal in Origin.—A. F. Perigal reports the case of a well-built man of twenty-four, who was admitted to hospital with symptoms of a severe attack of influenza of twenty-four hours' duration. He complained of pain in the back, legs, head, and especially behind the eyes. At the end of a week he was doing well in every way (although headache continued) when his temperature suddenly rose and diarrhœa set in, lasting a week. Widal's reaction was negative, and there were no distinct typhoid symptoms. In the third week his temperature rose to 105°, and he developed a hard red erysipelas-like swelling on the right cheek, which spread around the right eye and over the nose. He became very restless and was semi-comatose, throwing his hands above his head. When roused and questioned he appeared fairly intelligent, but answered gutturally. After sleeping a few hours he awoke with right hemiplegia and aphasia. The symptoms gradually passed into a meningitis type and he died in the fourth week. The autopsy revealed general meningitis. The interest in this case, says the author, lies in the early symptoms and their sudden onset in a strong, healthy subject, also in the fact that there were other cases of influenza in hospital at the time. Was this a case of influenza terminating in meningitis, or were the early symptoms those of commencing brain affection? Again, supposing the swelling of the face was true erysipelas, would this, considering the possibility of influenza, have been likely to cause meningitis, which apparently is a rare complication of erysipelas?

The Treatment of Bronchiectasis and of Chronic Bronchial Affections by Posture and by Respiratory Exercises.—W. Ewart says that the principle involved in postural treatment is the simple one of gravitation. The foot of the bed is raised and kept at a height of say fourteen inches or so from the floor. This allows of easy expectoration, and will often relieve spasmodic cough when all drugs are unavailing. The immediate result is great sense of relief, a diminution in the frequency and severity of the cough, a lessening of the sputum, a complete cessation of the gush of expectoration, and presumably the liberation of the affected pulmonary areas from entangling slime and from any further plugging with mucopus. The results are due (1) to the mechanical advantage of gravitation, and (2) to the stimulus to cough set up by the progress of the secretion as it reaches healthier and more excitable mucous surfaces; while other advantages are (3) that portions of the lung previously kept airless are enabled to expand, and (4) that the slanting posture, by carrying the weight of the abdominal organs upwards against the diaphragm, facilitates expectoration. A further advantage is that the time of day for emptying the chest can be selected. The various evils of accumulation are obviated or remedied. Local putrid fermentations, ulcerations, and infiltrations, collateral septic bronchopneumonic infections, and general septic contaminations are all guarded against. Cylindrical bronchiectases are more quickly relieved than the saccular. It is obvious that pulmonary abscesses and empyemata possessing only narrow fistulous communications with the bronchial system are susceptible only of partial benefit.

When there is no advanced tuberculosis—that is, in all early cases, particularly before middle age—the best curative treatment appears to be a combination of the postural method with well-planned respiratory exercises, whereby more and more of the previously hampered lung substance is restored to activity, and most of the space usurped by the dilatations may gradually be reclaimed by healthy pulmonary tissue.

British Medical Journal, July 13, 1901.

On the Evolution Myelopathic Albumosuria.—T. R. Bradshaw concludes that: The presence of the albumose in the urine is the earliest symptom of the disease, and may be observed for many months before there are any other indications of failing health, or any local signs of alterations in the skeleton. To generalize from the only case in which the point has been investigated, the albumose is first excreted in small amounts; but owing to the fact that at this stage the subject of the disease does not suffer any inconvenience from it, he is not likely to consult a physician, and so the urine is generally not examined until the albumose has risen to a large amount.

Infection by the Urine in Convalescence from Typhoid Fever.—T. Clifford Allbutt calls attention to this important subject. He speaks of a case recorded by Dr. Cushing in which the bacilli are said to have lived in the urine for a period of no less than five years! The bacilli in the stools, however, certainly do not survive long into convalescence, even if until convalescence. It has been demonstrated that tubercle bacilli are usually excreted by the kidneys without the formation of "tubercle" in the organ. And it is declared that typhoid bacilli, thus excreted, may come through in millions, and for a period long enough to poison a county. All physicians should see that the disinfection of the urine is carried out systematically in every case before the patient is allowed to mix again freely with his kind

Experimental Malaria: Recurrence after Nine Months. P. Thurburn Manson, as a result of the bites of mosquitos fed in Rome on a case of benign tertian ague, developed a double tertian fever. The first symptoms appeared after an incubation period of between ten and sixteen days. The illness lasted four days, when the presence of the parasite having been fully confirmed, ten grains of quinine were given. This drug was given from time to time for the next three months. The writer kept in normal health for nine months when prodromal symptoms of illness developed, and a definite malarial paroxysm again occurred. This attack proved to be simple benign tertian malaria, the original infection being of the double tertian type.

A Curious Method of Opium Poisoning.—J. A. Henton White reports the case of a baby of three months, who was brought to him very pale and cold, the pupils minutely contracted and in a stupid condition, from which it could be roused only with difficulty. The mother had put a pledget of cotton-wool, soaked in laudanum, in her tooth which was aching, and had then moistened the nipple of the baby's bottle several times in her mouth. The baby's stomach was washed out with very weak Condy's fluid, and a drop of liquid extract of belladonna was left in. The child was also given a small enema of black coffee, and it was roused and kept awake. The child showed the effects of the belladonna, and was given a warm bath. The next day it was quite well.

A Case of Ruptured Uterus in a Multipara.—J. Pollock Simpson reports this case. The patient was a woman, thirty-three years old, who while she was in labor cut off the forearm of the child. This part was presenting. Post-mortem examination showed the child and placenta in the peritoneal cavity, with the exception of the stump of the right arm and the head, which were in the cavity of the uterus. The peritoneal cavity was filled with blood-clot and fluid blood. The rupture, about four inches in length, was on the left side, just at the point where the peritoneum is reflected to form the broad ligament. The edges of the tear were uneven, but did not involve the fundus nor the vaginal portion. The uterine tissue appeared healthy as also did the other organs of the body. The writer has the following theory, as to the cause of the rupture: The head of the child was lying in the left ilio-hypogastric region with its back to the outlet of the pelvis; this being so and the body being doubled on itself, the feet would be in the region of the left sacro-iliac synchondrosis. When the mother amputated the arm it produced strong reflex action in the child, causing it to plunge with its feet against the uterine walls, which would be in a relaxed and weakened condition, causing rupture at this point. Thus it escaped feet first into the peritoneal cavity, and dragged the placenta with it.

Leucoma or Leucoplakia of the Vulva and Cancer.—H. T. Butlin states that white areas of more or less horny epithelium occur on the vulva just as they do on the buccal mucous membrane. He reports three cases. The first was an unmarried woman, forty-four years old. A large part of the surface of the greater and lesser labia were covered with numerous white areas, some of which were quite thin and bluish white; others, thick and opaque. Later, there developed an indurated ulcer at the upper part of the right labium majus in the midst of the white plaques. This ulcer had all the appearance of epithelioma in an early stage. She did not have this removed, and in about six months she died. The cause of death would seem to be pernicious anemia in connection with malignant disease of the vulva and probably of the glands. The second patient, a widow aged seventy-three, was suffering from a circular ulcerated epithelioma of the right labium majus. The ulcer was situated in a plaque of very thin white leucoma and there were similar areas covering all the upper part of both labia on both sides, and the central part of the vulva about the orifice of the urethra and the clitoris. Microscopic sections showed the ulcer to be squamous-celled carcinoma. The third patient was an unmarried woman of sixty-six years. A large part of the left labium majus had been removed for what was reported to be an epithelial cancer. She was at this time suffering from secondary affection of the glands in the groin, the pelvis, and abdomen, quite beyond the reach of any operation. The right labium majus was covered with thick white areas of leucoma of the mucous surface. The plaques in these cases form only on the mucous surface, not on the skin. They are precisely similar in appearance, feel, and variety of form to the white plaques which form upon the mucous surface of the mouth. In more than one instance, the vulva and the mouth have been attacked in the same patient. There is reason to believe that it is the same disease in both situations. If so, the influence of tobacco and of the direct contact of alcohol in producing the disease loses some of its importance. Syphilis was not suspected in these patients.

Berliner klinische Wochenschrift, July 1, 1901.

The Home Treatment of the Mentally Diseased.—C. Moeli says that home treatment in mental cases may be carried on either entirely independently and without any institutional connection, or as a grouping together of the households of patients in some definite locality around an institution intended for exceptional cases as a centre, or lastly, in direct connection with the ordinary asylum treatment. These forms, in a way, represent the transition from strict asylum seclusion to complete independence, and are well adapted, in suitable cases, to promote recovery through the more interesting and healthful life they afford, and are also adapted to dispel popular prejudices concerning mental invalids.

Vegetarian Diet for the Masses and the Capacity Balance.—Baelz gives the results of observations he has made on the Japanese, among whom the lower classes are almost entirely vegetarians. They are so, not from choice or principle, however, but from necessity, since whenever they are able they buy a little meat or fish, and regard it as a great luxury. Their main article of diet is not rice, as usually supposed, because this is too expensive, and is used mainly by the well-to-do, but barley and buckwheat and the soya bean, which contains twice as much albumin as the best beef, and costs one-quarter as much, while in addition it contains twenty per cent. of fat. The fallacy of Voit's dictum that 120 gm. of albumin daily are necessary for an adult is shown, for, as evidenced by the habits of the Japaness for generations, it is twenty to thirty per cent. too high, while it is demonstrated that a race may live on an almost exclusively vegetable diet and yet be capable of vigorous and protracted labor. The prevailing type of metabolism investigation, in which purely arithmetical results of analysis of the income and outgo are made, is unreliable and does not give a true idea of the values of diets, etc., for different conditions may produce almost identical results in figures. The disposition of the individual and, therefore, his capacity for work may vary widely, and therefore the author proposes a new method of conducting such experiments, which shall include a study of this factor, and suggests the designation of "capacity balance" for its results.

Munchener medicinische Wochenschrift, July 2, 1901.

The Injection Treatment of Syphilis.—M. Stern, in a very thoughtful article recommends hypodermatic mercurial injections as affording a valuable form of treatment in many cases. They are especially useful when other affections of the skin or digestive tract make the administration of mercury by inunctions or in pill form unadvisable, and in grave cases where important organs are attacked and quick energetic therapy is required. In addition, by this means a doubtful diagnosis may often be speedily cleared up, and cases that have resisted other

treatment or relapsed may respond to injections. In addition, much better results frequently follow alternation of various modes of administration of the drug, and the injections are of great use in these cases. The soluble preparations are to be preferred, and for routine use one-half per cent. sublimate solution, thrown into the muscles, is recommended as the safest. The next best is the salicylate of mercury, but caution is necessary in using this while the insoluble salts are not adapted for daily practice. Like the virus of the disease itself, mercury reacts differently on different patients, and even on the same patient at different times, so careful individualization is always necessary, and every additional therapeutic measure is sure to be found useful at some time.

Syphilitic Sciatica and Its Treatment.—F. Mendal describes three cases in which the sciatica, while giving the symptoms of the ordinary type, was evidently, as shown by the history, other lesions, and the result of treatment, luetic in nature. All three patients had resisted all therapy, and in consequence of the pain and insomnia were greatly reduced in flesh and strength. The results of mercurial treatment were almost miraculous, mercury salicylate was given hypodermatically in the glutealr egion, and the first injection gave great relief in each case, while five or six repetitions completed the cure.

A Case of Poisoning by Male Fern.—W. Gotthilf was called to a patient who was supposed to have had an apoplectic attack. He was found comatose, the whole body in convulsion with pronounced trisonus, pulse rapid and barely perceptible. Camphor and morphine were given hypodermatically, whereupon the patient soon recovered consciousness and a vascular lesion could be excluded, but it was only with a good deal of difficulty that the information was elicited that three days previously, on the advice of a quack, the patient had taken a large amount of a tapeworm remedy. This was found to be extract of male fern, and as the patient had omitted to follow it up with a cathartic, he had suffered a severe intoxication. Recovery was complete on the fourth day.

Obstipation Lasting Thirty-five Days with Uncomplicated Intestinal Obstruction.—P. Ostermaier's patient was a girl of 14, who for several years had been subject to attacks of constipation lasting six to eight days. Two months before coming under observation she passed through a slight attack of articular rheumatism. When seen, eight days had elapsed without the passage of any stools or flatus, but the general condition was undisturbed. A large fecal tumor was made out in the sigmoid flexure, and for sixteen days five or six high irrigations were made daily, each one bringing away small amounts of vegetable matter. Croton oil, colocynth, belladonna, and atropin were given in large doses, but proved ineffectual, the frequent small irrigations were replaced by much larger ones, given twice a day. Sixty liters were used at each session, and twenty-two were given in all, the return flow each time containing fecal masses. Finally a dose of castor oil brought away copious scyballous masses, and on the thirty-fifth day the tumor had entirely disappeared. For the first twelve days the occlusion had given no symptoms, then, up to the twenty-fifth day, there were slowly increasing anorexia, lassitude and occasional vomiting, which symptoms, however, immediately receded after the first large injection was given. At no time was the abdomen tympanitic, showing how completely the blood may absorb the intestinal gases.

Deutsche med. Wochenschrift, June 27 and July 4, 1901.

Trauma and Extrauterine Pregnancy.—L. Seeligmann believes that, in addition to inflammatory processes of the adnexa, trauma is a frequent cause of extra-uterine gestation and mentions five cases in which the connection could be satisfactorily demonstrated. The patients had all passed through uncomplicated previous pregnancies, and eight to ten days after the last menstruation sustained a trauma, usually a fall, which subjected the pelvis to considerable concussion. The author's theory is that the jar throws the freshly impregnated ovum out of the fimbriated extremity of the tube, or causes it to become deeply imbedded in the lining epithelium, and to proceed with its development in that situation.

A Case of Sepsis with Otitis and Sinus Thrombosis.—Schnelle reports a case in which it was hard to tell whether the mastoid condition was merely one of a number of manifestations of general sepsis or whether it was itself the starting point for the suppurative process that finally caused the patient's death. The patient, a young man, first had a cellulitis of the hand, which did well without incision, but was soon after followed by dizziness and buzzing and pain in the right ear. Soon after a paracentesis of the drum membrane had liberated a large amount of pus from the inner ear, the ankles became swollen and painful and the temperature rose, but the trouble receded under the salicylates, and was therefore considered rheumatic. A little later it was thought advisable to open the mastoid, which on exposure was found to be highly necrotic; several secondary operations had be to done, and the patient finally died with the manifestations of general sepsis. The autopsy showed metastasis in the lungs and heart, and confirmed the author's belief that the condition had been one of latent sepsis from the beginning, and that the cellulitis of the hand, the otitis and joint involvement were all only incidents in the progress of the disease.

The Differentiation of Human and Animal Blood by the Aid of a Specific Serum.—E. Ziemke refers to the investigations of Wasserman, Schütze and Uhlenhuth, who have shown that by injecting rabbits with human blood a change is produced in the rabbit's serum, made evident by the fact that when added to dilute human blood a turbidity is caused, which does not appear with the blood of any other animal except the monkey, and describes some further tests he has made to determine the applicability of the reaction for forensic purposes. Positive results were obtained with fresh blood, dried blood, blood stains in cloth, blood in garden soil, blood from a person poisoned with carbonic oxide, blood on steel implements, blood from the wall of a cellar, blood in wood, blood in glass, blood on paper, the blood of a three-day-old corpse, and putrid blood. The stains in several instances were ten or more years old, and, where possible, control tests were made on the blood of the common domestic animals. In every case except one a positive result was obtained with the human blood preparations, while the animal tests were all negative; the one failure is attributed to the fact that the stain tested, which dated back to 1883, did not yield any extractive to the soda solution in which it was soaked.

"Cancer à Deux" and the Infection of Cancer.—R. Behla contributes a large number of cases in which man and wife died of cancer within a few years of each other, and says that, even admitting the possibility of transplantation or heredity or a common exposure to the same injurious influences, there still remains a considerable proportion of cases where these factors can be excluded and where direct transmission from person to person seems indubitable. Definite prophylactic rules cannot yet be made, but all secretions should be disinfected, as well as all instruments, utensils, etc., used by cancer patients, and attendants should sterilize their hands after dressing, and surgeons after operating on such growths. The possibility of the infectious nature of the disease is too great to be neglected, and as many precautions as possible should always be taken.

"Chlorine Acne" an Occupational Skin Disease.—Bettman describes at length a particularly severe type of acne occurring among the workmen in a large chemical works. The patients had all been engaged in cleaning a so-called "tower," usually filled with hydrochloric acid gas, and while the exact nature of the agent causing the trouble could not be determined, it seemed likely that some combination was formed between the nascent chlorine gas and the tar used to coat the tanks, which products could well be assumed to be volatile and highly poisonous. The intoxication must have taken place through inhalation, for even a foreman who did none of the actual work was affected. The manifestations of the disease are given in great detail, but, briefly, it may be said to consist in the development of very large and numerous pustules, with exaggerated comedo formation and roughening and pigmentation of the skin. All parts of the body, including the hairy scalp, are affected, and while no secondary symptoms were noted, and the patients are not disabled the lesion is serious in that it is intensely disfiguring and strongly resembles Darier's disease. Treatment is not encouraging, but the disease usually terminates in recovery after many months, and does not leave permanent traces.

French Journals.

Experimental Tuberculosis.—Lannelongue, after completing his previous experiments on the evolution of experimental tuberculosis relative to the influence of climate, has recently studied from the same point of view the effects of insufficient alimentation, of the inhalation of dust, and of muscular work. He inoculated one hundred male guinea pigs in the right pleura with a culture of Koch's bacillus. These animals he arranged in groups according to their weight, some of which he used as control, while the others were subjected to these various influences. The ones which were badly nourished, exposed to dust, and those made to work, all succumbed far more readily to tuberculosis than the control animals which were guarded from these influences. The state of health of the latter class demonstrated irrefutably the rôle which unfavorable hygienic conditions play in the course of the tuberculous process.—*Bulletin Général de Thérapeutique*, June 8, 1901.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SIR R. D. POWELL ON ACUTE HEART FAILURE—POSTERIOR VAGINAL CŒLIOTOMY—HOSPITALS AND ANTIVIVOS—TEACHING OF ANÆSTHETICS—SCOTCH G. P.'S AND OPEN SHOPS—LORD LISTER AT ST. THOMAS'S—SIR H. ROSCOE—ELECTIONS.

LONDON, July 5, 1901.

THE Cavendish Lecture was delivered on the 21st ult. by Sir R. Douglas Powell, Bart., who devoted it to "Acute Cardiac Failure." This he admitted might be a misleading phrase for the culmination, in temporary or permanent arrest of the cardiac function, of a variety of conditions affecting texture, nerve power, or muscular energy. We must regard the heart as a part, differentiated for special reasons, of a complete cardiovascular tubal system containing the blood, and this in relation with a highly specialized nervous system.

The lecturer then passed to the more clinical and practical considerations. The first obvious cause of failure is injury *c. g.* rupture of an aortic valve, embolism, or over-taxation. Speaking of young people and healthy hearts, he said acute cardiac distress is very common in these days of athletic competition, but fatal cases are rare, and we observe, as a rule, only the after effects of incomplete failure. Vomiting and later anæmia are prominent effects attributed by the lecturer to accumulation in the blood of the products of metabolism, as are also some gastro-intestinal attacks in sedentary persons who suddenly take to exhausting exercises. Further proofs of altered blood were cited, as seen in persons dying from excessive exercise and in hunted animals; of those the most obvious are increased liquidity, absence of *post mortem* clotting, and darkened color. The treatment involves complete rest for several weeks and often months of careful supervision. The younger the patient the sooner and more complete the recovery, but some may suffer from attacks of palpitation and pain after slight exertion for a long time, sometimes for years. Heart fatigue from acute disease was but briefly touched upon, the lecturer having treated of it in his Lumleian lectures last year, and to discuss its treatment adequately under such varying conditions would be to discuss the whole management of these diseases. But some indications were mentioned, as (*a*) maloxygenated blood supply; (*b*) excessive weight of blood burdening the heart, and calling for depletion from the venous side; (*c*) exhausted innervation and (*d*) pulmonary obstruction met with in pneumonia, typhoid fever, and asthma; for these strychnine subcutaneously was pronounced best; (*e*) the changes in the heart muscle incidental chiefly to pyrexia which are best warded off by mitigation of the pyrexia. Here the lecturer said he had found hot water better than cold for sponging, the surface circulation being more facilitated, heat more rapidly lost, and perspiration encouraged, all tending to lighten the burden of the heart.

Angina pectoris was regarded as, in most cases, a functional disease—a cardiovascular neurosis; but in some cases there is a background of unsound heart—aortic regurgitation, aneurism, senile fibrofatty hypertrophy, uræmic heart, coronary disease, and the like. The immediate remedies for the anginal attacks are in most cases therefore antispasmodics and sedatives, such as amyl, trinitrine, and opium, directed against the arterial spasm, which is so important a factor in the attack. In coronary cases, carefully regulated exercises and, in old persons especially, the regular use of oxygen inhalations help to maintain cardiac nutrition and ward off attacks. But caution is required to prevent cardiac fatigue, and the periods of gentle exercise must be very short. This lesson was enforced by mentioning the case of a medical friend who, after a course of special exercises, declared himself a new man who could walk miles, but he died suddenly a fortnight afterwards. Cramp in the legs is common in old people with atheromatous vessels, after fatiguing exercise. It is due to the imperfect nutritional change allowed by narrowed arteries. So we may have cramp of the heart muscle, which is apt to be fatal. Cramp does not always come on at once, but may often be postponed until the night. So it is with angina or syncope, induced by fatigue or excitement in the day and proving fatal in the night. Sir D. Powell concluded with reference to "cardiac hesitancy" not amounting to intermittency, and which he was inclined to regard as allied to *petit mal*, but which often recovers under rest from mental pressure, out-door life, and remedies for anæmia.

In the adjourned discussion on Posterior Vaginal Cœliotomy (the first portion of which was reviewed in a letter you have already published), Mr. Jordan said he had long advocated the vaginal route. In suitable cases it avoided the dangers of abdominal section. He had operated on above sixty cases without a death, and only once seen any trouble follow. The patients could get up and resume work earlier than after abdominal incision, and there was not the scar, an advantage in case of future pregnancy. Both these points were important, especially to poor women. The vagina could be made aseptic as easily as the abdominal wall, and those who denied this should produce proofs.

Dr. Macnaughton-Jones said the first point was diagnosis. Some cases could only be dealt with by abdominal cœliotomy; in others the vaginal operation was the method of selection.

Dr. Alexander, replying, said he did not regard the proximity of the rectum as an objection. The field of operation was as close to it in one route as the other. The vulsellum effectually closed the os against infection. After operation the vagina was packed with antiseptic gauze, which kept it sweet and drained away any discharge which formed. Stitches were not necessary. Hemorrhage was prevented by clamps. The chance of hernia was avoided, and that occurred after abdominal sections even by the latest methods of operating—it was always the latest which was supposed to obviate this. But a certain proportion of hernias occurred after all methods, and a considerable time must elapse before it could be certain there would not be a hernia in any case of abdominal section.

The attempt to spoil the Hospital Sunday Collection, which I mentioned to you, has not proved very successful, and has covered the antivivisectionists with no little obloquy. In one church I am able to testify that the clergyman was not contented to pass by the attempt, but told his hearers plainly that he had read the leaflet which had been distributed outside his church, as well as much other matter on the subject, and he could assure them that a number of the statements made were quite untrue. It was good to hear him repeat again and again that the statements of the leaflet were untrue. Mr. Stephen Coleridge is thus once more told that he has been circulating falsehoods, but he must by this time be hardened to hear the charge with indifference.

Another clergyman took a different course: Archdeacon Wilberforce told his audience that he had been troubled on the question for the last twenty years, and then proceeded to retail Mr. Coleridge's falsehoods, and even to embellish them with gush and nonsense. Further he said that "according to the official Blue Book more than 10,000 animals were done to death during last year, mostly under circumstances of exquisite and prolonged torture." Other equally absurd and untruthful statements, wherever he picked them up, induced the Archdeacon to tell his congregation he had decided to have two collections, one for the Hospital Sunday Fund without conditions, and the other for a hospital chosen by Lord Llangattock. This enlightened Lord has nominated a hospital standing on his own property.

That property he holds as the result of one of his forbears squatting on and enclosing common ground when the public was less alive to such encroachments. We might, therefore, have expected him to devote a trifle out of the income it yields to the local hospital rather than a collection obtained by such methods. But let it pass. He is the first of his family to get a peerage, and has not digested the adage *noblesse oblige*. That is obvious enough from the course he has taken on this question.

As to the Archdeacon, he is so accustomed to express his views in strong language that he cannot expect those on whom he pours out his wrath in false charges to confine themselves to remonstrances against his inaccurate statements. Some of them are saying that it is "much more shocking for an archdeacon than for a barrister to tell lies." For my part I am contented to remind him of the commandment "thou shalt not bear false witness against thy neighbor." He can hardly plead that even an archdeacon is justified in doing so on hearsay evidence—even though tendered by a peer and a barrister against a physiologist.

The teaching of anæsthetics has been exciting some attention—perhaps I should say the want of such teaching. The anæsthetists at our hospitals, who should give instruction on the subject as well as the demonstration of their methods involved in their routine work, want to have a course of lectures on the theory and practice of anæsthesia made compulsory. The Conjoint Board has so far fallen in with their views as to circularize the hospitals, asking what provision they make for instruction on the subject. It is impossible to deny the importance of a knowledge of anæsthetics and their uses to every medical man, for any one in practice may be

obliged sometimes to administer them. It does not, however, follow that students should be compelled to listen to and pay for a course of lectures on the subject. I am no despiser of didactic lectures, but students have many courses to attend, and it may be that other subjects have even greater claims; for, after all, few lessons are necessary as a preliminary to administration under the eye of the anæsthetist and this opportunity ought to be given to every student.

Practitioners in the west of Scotland feel aggrieved that the Medical Council declined to receive the deputation about the employment of unqualified assistants as dispensers, but as there was a case under consideration at the time, reference to which could scarcely be avoided, I think the Council was quite right, for it is most important that its judicial functions should not appear to be influenced in such a manner. Those who feared their rights would be in danger would have expended their money more wisely perhaps by instructing counsel to appear than by sending a deputation. There is another point. For some three hundred years Scotch general practitioners have had the right of selling drugs and poisons. The privilege is secured in some of the Scotch diplomas, and the custom has continued with many of keeping open shop. The pharmacy acts restricted the sale of certain scheduled poisons, and the practitioners seem to have been willing that this should be the case, and always to have kept within that rule, but, of course, they cannot be prevented from dispensing or selling other drugs and of employing unqualified assistants. Opinions differ as to whether this privilege is useful to the public, but it certainly ought not to be taken away by a side-wind.

Lord Lister formally opened the new operating theatres and children's ward on the 20th ult. In a speech, on the occasion, he alluded to attempts to depreciate hospitals as only pardonable by reason of the gross ignorance of those who make them.

Sir H. Roscoe has been elected Vice-Chancellor of the London University for the ensuing year.

As to the coming election for the General Medical Council it has been arranged for all the seats to be vacated at the same time, so that one election only may be needed.

The election to the Council of the College of Surgeons took place yesterday afternoon. The three vacancies were filled by the re-election of Messrs. Robson and Cheyne and the election of Mr. Lucas.

THE AMERICAN MEDICAL TEMPERANCE ASSOCIATION AND PROFESSOR ATWATER.

To the Editor of the Medical Record.

SIR: It will be of interest to your readers to understand the position which the American Medical Temperance Association has been forced to take in regard to the conclusions on alcohol asserted by Prof. Atwater. Our Association has been in existence over ten years with the special object of ascertaining the facts concerning alcohol and its uses in medicine. We have no controversy with anyone, or with any opinions that are based on experiments and reliable experience. Recently there has sprung up in certain circles an offensive dogmatism asserting that the alcoholic subject has been settled by the work of Prof. Atwater. This has assumed such magnitude in certain circles that all conclusions to the contrary are ignored as the work of enthusiasts. No recognition is given to the number of prominent scientists who have pointed out the errors of Atwater's conclusions or that any other facts could possibly be true. This Association has thus been forced to go on record as opposed to conclusions based on tables, which flatly contradict the author's statements. The alcohol question is far too great for any one man, or one set of experiments to determine, and while this Association welcomes all investigations and theories that are apparently based on facts, it protests against the assumption that the conclusions of Atwater are final in regard to the food value of alcohol. Very truly yours,

T. D. CROTHERS, M.D.,
Sec'y of A. M. T. A.

HARTFORD, CONN., July 20, 1901.

THE SEGREGATION OF LEPERS.

To the Editor of the Medical Record.

SIR: The editor of the *Journal of Tropical Medicine*, in the issue of May 1, takes exception to what I said in my letter to the MEDICAL RECORD of April 6, "Shall Lepers Marry," regarding Great Britain's breach of international duty in shipping lepers and relatives of lepers, thus sowing the seeds of the Hindu disease all over the world. What I stated in my reply to a countryman of his in India was the naked truth. Beaven Rake, of British Columbia, near enough to contaminate the United States, made it known to the world long ago.

Allow me to observe further that according to the *Medical Press* of London, July 3, "the loathsome disease is on the wane in the Great Eastern dependency of Great Britain, to an extent that is not generally recognized by the dominant nation here at home. In 1898 the Indian Government passed an act providing for the segregation of mendicant lepers and forbidding lepers to handle food or to carry on trades dangerous to the community. It has recently been resolved to enforce that measure in Bengal, presumably as an experiment to test the feeling of the native population. In Nepaul it has been stated that a person found to be suffering from leprosy is sometimes buried alive by the Brahmins, and in Sumatra, at times, the relatives of a leper burn him to death in his house, pushing him back into the flames should he attempt to escape. The Leper Mission does its best to care for about one million lepers, said to exist in India, China, and Japan. In India the housing and food of an adult leper can be provided at the modest rate of five pounds a year. As a preventable disease, leprosy can be banished from the face of the earth by the strenuous application of modern preventive science, but, unhappily, it seems likely to linger for generations in India, the favored home, under present conditions, of cholera, enteric fever, plague, and other specific scourges of mankind."

Right here I should like to ask the British leprologists why leprosy must linger in India for generations, and also their views as to compulsory isolation and its practicability among the outcasts of that country. It seems that there are some people in London who oppose compulsory isolation. I should like to know what arguments besides those of expediency (the five pounds per adult leper a year) they have against it; or, if they have no arguments, what cause impels them to oppose a thing which, as even the history of the middle ages shows, can eradicate the disease.

I suppose that there are still people who dumbly, without knowing why, look at the bacillus as the element from which a remedy and cure may be expected. That same bacillus has done nothing for the leper in a quarter of a century.

I should like to ask also what those leprologists of Great Britain, as are known to be competent, think of the international isolation question (en bloc), and also what can be the real motives of those who oppose compulsory isolation—for instance, Jonathan Hutchinson, Sir Joseph Fayrer, *et al.*

China has as many lepers as British India. Yet Dr. Y. G. Kerr, of Canton, wrote me not long ago regarding a suggestion, or rather appeal, for all governments to form an international commission on leprosy, that "such a commission would be the basis for action (to suppress and prevent the disease), and would, no doubt, unite the efforts and energies of many philanthropic influences, which might otherwise do nothing, or, acting singly, might accomplish very little. I assure you that the establishment of government homes for lepers would be a great boon to them, and be the means of doing much good. And the Chinese, both officials and business men, would aid by yearly contributions."

At the same time that I wrote to Dr. Kerr, I explained my plan to the editor of the *Indian Medical Gazette*, of Calcutta. All problems concerning leprosy, especially of emigration, should be submitted to an international tribunal. So by common and universal efforts against the dreadful scourge, it might be, in a comparatively short time, wiped off from the surface of the world. It is certainly worth the while to fight some years for such a tremendous result. Mankind certainly at no time of history has fought for a greater object.

Such a momentous matter cannot help to appeal to the sympathies of the editor of *Tropical Medicine*, a journal published in a country which rules over one that suffers more than even China from the terror against which we continue the fight. May we hope that he will use the influence of his pages to obtain from the Parliamentary leader an expression of opinion as to this matter.

ALBERT S. ASHMEAD, M.D.

NEW YORK.

The Care of Hypodermic Needles.—Dohn notes that it is not necessary to throw away hypodermic needles that have been used, for if the canal has become obstructed, the needle can be made as good as new by simply boiling it for ten minutes in a solution of carbonate of soda the precipitate which has collected on it is dissolved by this method and the primitive brilliancy is restored.—*Brooklyn General of Therapeutics*, June 8, 1901.

Book Reviews.

ECZEMA, with an Analysis of Eight Thousand Cases of the Disease. By L. DUNCAN BULKLEY, A.M., M.D., Physician to the New York Skin and Cancer Hospital, etc. Third Edition of "Eczema and Its Management." Entirely Rewritten. New York and London: G. P. Putnam's Sons. 1901.

THOUGH primarily intended as a student's manual, this little volume is really an excellent monograph upon that common and often refractory disease, eczema. The subject is treated in the systematic manner which is so necessary in a book of this kind, and the student will find it an excellent companion during his work in the clinic. To the practitioner, also, it will be a useful and suggestive work to have at hand, and an authoritative guide in the treatment of a disease the recommended remedies for which are legion. This book is an excellent example of what a special monograph should be, and the accomplished author has done a service to the profession in preparing a third edition of it.

THE STUDENT'S MANUAL OF VENEREAL DISEASES. By F. R. STURGIS, M.D., sometime Clinical Professor of Venereal Diseases in the Medical Department of the University of the City of New York, formerly one of the Visiting Surgeons to the Charity Hospital, Blackwell's Island, Department of Venereals, Member of the American Association of Genito-Urinary Surgeons, etc. Seventh Edition, Revised and in part Rewritten by F. R. STURGIS, M.D., and FOLLEN CABOT, M.D., Instructor in Genito-Urinary and Venereal Diseases in the Cornell University Medical College; Genito-Urinary Surgeon to Bellevue Hospital, Out-patients' Department; Visiting Dermatologist to the New York City Charity Hospital; Lecturer on Venereal and Genito-Urinary Diseases in the University of Vermont. Philadelphia: P. Blakiston's Son & Co., 1901.

THIS volume was written for the medical student over twenty years ago, and has gone through six editions up to the present time. This, the seventh, has been largely rewritten and thoroughly revised, and we can confidently recommend it as a guide to the beginner. The text has been italicized with rare judgment, the subject-matter bristles with practical points, the prescriptions are given in full, and are well chosen. As a concise and practical teaching book, it will not fail to suit the reader.

ATLAS OF THE NERVOUS SYSTEM, Including an Epitome of the Anatomy, Pathology, and Treatment. By Dr. CHRISTFRIED JAKOB, Head of the Pathological Institute for Nervous and Mental Diseases at the University of Buenos Ayres, etc., with a Preface by Dr. A. VON STRÜMPELL, Director of the Medical Clinic, Erlangen. Authorized Translation from the Second Revised German Edition. Edited by EDWARD D. FISHER, M.D. With 112 Colored Lithographic Figures, and 130 Other Illustrations. Philadelphia and London: W. B. Saunders, 1901.

THIS volume is one of the most recent members of a very excellent series of atlases which have been published at short intervals. The chief characteristic of this one, as well as the others, is the remarkably fine colored illustrations, in this case of the anatomy of the nervous system. Those in this volume which show the gross appearances of the brain are little short of perfect, and opposite each is a key-plan drawn in outline. The descriptions in the text are terse and well translated, and add to the value of the volume as a text-book. We must also commend the colored illustrations of different microscopic pathological appearances in nervous tissue. This series of atlases affords a rapid way of acquiring a good deal of information, and is valuable from many points of view, though naturally they can not take the place of the more extensive works.

SELECTED RESEARCHES IN PATHOLOGY. By ALEXANDER GLEN AULD, M.D., M.R.C.P. London: J. & A. Churchill; and Philadelphia: P. Blakiston's Son & Co. 1901.

IN a volume of some 150 pages the author has grouped a series of seven monographs, upon various pathological subjects, which have appeared from time to time during the past few years in the English periodicals and Society Transactions and which represent the result of original work in several fields of pathology, but more especially in that of pathological histology. The articles all show the evidences of careful and painstaking study and of thoughtful reasoning, and constitute real additions to our knowledge regarding the obscure points which they attempt to elucidate. The subjects of the monographs include emphysema, pneumonia, Bright's disease, splenic anæmia, acholuric jaundice, Addison's disease, atheroma, and aneurism. The paper on pneumonia deals with the histopathology of the disease, the bacillus pneumoniæ and the action of its toxins in rabbits. The other six articles represent the authors' studies chiefly in the field of pathological histology but also to some extent in experimental pathology.

The papers upon atheroma and aneurism are the product of the associated work of Dr. Auld and the late Professor Coats. In these the writers have (rather unfortunately, we think) thought best to use the term atheroma to denote the whole process of arteriosclerosis, and justify this use of the term upon the score of its being convenient and non-committal, although they hold with Virchow that the primary lesion is a productive inflammation of the subendothelial connective tissue of the intima, and is therefore more correctly named "endarteritis chronica deformans," which is the term Virchow originally applied to it.

Quite apart from their scientific value, the monographs are worthy of careful reading as examples of clear, concise, and polished diction.

PROGRESSIVE MEDICINE, a quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, assisted by H. R. M. LANDIS. Vol. I., March; Vol. II., June. Philadelphia and New York: Lea Brothers & Co., 1901.

THE first volume contains surgery of the head, neck and chest, infectious diseases, diseases of children, pathology, laryngology, rhinology and otology. The second, surgery of the abdomen, including hernia, gynecology, disease of the blood and ductless glands, the hemorrhagic diseases, metabolic diseases and ophthalmology.

The first article in Vol. I. by J. Chalmers DaCosta, contains 152 pages, and is divided into the surgery of the various regions of the head and chest, operations on the face, neck, lips, tongue, and jaws being considered together. The first article in Vol. II. by Dr. Wm. B. Coley, contains 176 pages, beginning with the radical cure of large umbilical hernia, then of intestinal surgery, then successively, surgery of the intestines, stomach, liver, pancreas, spleen, appendix, etc.

The portion relating to intestinal surgery is beautifully illustrated, showing the stages and sutures in intestinal anastomosis. These, as well as the following articles, are almost exhaustive so far as contemporaneous literature is concerned, and give an excellent résumé of advances and present state of science relating to the various conditions.

There is no evidence of falling off in the character of the work produced, and the publishers may felicitate themselves upon putting out a well-made quarterly.

MANUAL OF DISEASES OF THE EAR, Including those of the Nose and Throat in Relation to the Ear, for the use of Students and Practitioners of Medicine. By THOMAS BARR, M.D., Lecturer on Diseases of the Ear, Glasgow University, etc., etc. Third Edition Revised and Partially Rewritten, with two hundred and thirty-six Illustrations. Glasgow: James Maclehose & Sons, 1901.

THIS satisfactory handbook has gone through two editions in England, and its third now appears. Otology for the student and practitioner must usually be offered in general terms and rather broadly, since there is probably no branch which requires so high a degree of specialization if one wishes to be an expert. The general worker and the surgeon need a certain amount of information on diseases of the ear, especially in regard to making a diagnosis, but only the expert who devotes his whole time to otology is in a position to undertake the more intricate operative work. The present volume is a very good one for the general practitioner, and is also sufficiently detailed to make an interesting work of reference for the specialist. The author assumes an advanced position in regard to the treatment of mastoid disease and its sequelæ, and he devotes considerable space to the discussion of the latter. The illustrations are as a rule good, and there is a valuable bibliographical index.

PRINCIPLES OF SURGERY. By N. SENN, M.D., LL.D., Professor of Surgery in Rush Medical College, University of Chicago, Attending Surgeon to the Presbyterian Hospital, etc. Third edition, Thoroughly Revised, Illustrated. Philadelphia and Chicago: F. A. Davis Co., 1901.

THE first edition of this work immediately became a popular text-book, and this splendid revision will undoubtedly maintain the reputation of its predecessor. Considerable new material has been added, and much of the book has been rewritten in order to allow the inclusion of descriptions of the valuable work in surgical pathology and bacteriology which has been done in the past few years. The book is one of the best on the subject,

Clinical Department.

TWO CASES OF TYPHOID FEVER, ONE COMPLICATED WITH AN ACUTE NEPHRITIS AND LOBAR PNEUMONIA; THE OTHER WITH MALARIA (TERTIAN) AND SCARLET FEVER; WITH A DESCRIPTION OF THE ICE-PACK AS USED IN THESE CASES.

By LESTER LAURENS ROOS, M. D.
HOUSE PHYSICIAN, GERMAN HOSPITAL OF BROOKLYN.

THE following two cases are reported because of the complications which attended the course of the disease. In the first the typhoid condition was hidden for a number of days, while in the other a condition which many deny was found. These cases occurred during the service of Dr. J. Fuhs, to whom I owe permission to report them.

In both cases the Brandt method of tubbing was discarded and the ice-pack used in its stead. A brief description of the pack as employed in the hospital would not be amiss and is as follows:

The patient's temperature is taken every four hours, and if above 102.2° the pack is ordered. If the urinary organs are in perfect condition and the laboratory report is negative, the pack is preceded and followed by Spts. frumenti ℥ss; if, however, there is any trace of a nephritic condition, four ounces of hot milk is substituted for the whiskey, and repeated at each change of the sheets.

The bed is prepared as though the patient was to receive a sponge bath, that is, the mattress is covered by a double thickness of rubber sheeting and upon this the blankets are placed.

The patient is placed upon a sheet, which has been wrung out of water at 70° F., and covered entirely by it. Blankets which have been soaked in the same water are placed above the sheets. An ice-bag is placed to the head. One-half hour later the sheets and blankets are changed and wrung out of water at 60° F. The next half hour, the sheets and blankets are changed and wrung out of water at 50° F. At this time, a quantity of cracked ice is placed in the axillary spaces and along both lower limbs. This is left on for another half hour, when the pack is changed to 40° F. and the ice is reapplied. The entire pack consumes two hours.

The temperature is taken one-half hour later and in the majority of cases there is a drop in the temperature of anywhere from 1½° to 4½° or 5° F. Not only do we find the drop greater than after the tub baths, but there is an entire absence of the shock due to the sudden immersion of the patient into the tub of water, and of the shivering and cyanosis which are marked in this method.

The great danger of perforation and hemorrhage is entirely obviated. The temperature not only remains down longer, but it keeps on going down for a number of hours after the application of the pack.

CASE I.—P. T., aged 23, grocer's clerk, German, applied for admission on Oct. 22, 1900. He gave the following history:

He is single, and has a negative family history. He had diphtheria(?) about 5 years ago, but was confined to bed only a short while. Otherwise he has been perfectly healthy until the present time.

Two days ago, after having slept all night near an open window, he had a severe chill on arising, which lasted about forty minutes. This made him so weak that he returned to bed. Later in the afternoon he felt feverish and had a dry cough. He also says he had a slight diarrhœa for a number of days.

Physical examination showed dulness at the left apex and also in the axillary line. There was bronchial voice and breathing over the same area. The local fremitus was increased. The cough was accompanied by the typical rusty sputum. The temperature was 103°; respiration, 28; pulse, 108. A diagnosis of lobular pneumonia was made and treatment was instituted. Examination of the urine showed twenty per cent. albumin and traces of sugar. The report of the sputum analysis showed the pneumococcus in abundance.

On October 24 the patient complained of pain in the abdomen when moving. Examination revealed nothing excepting a slight tenderness. The temperature at 8 A. M. was 102.4°; at 4 P. M. 103.8°.

On October 26 the signs in the chest were growing less marked, but as the pain in the abdomen had not ceased another examination was made. This time there was great tenderness over the entire abdomen and especially in the sigmoid region. There was distention and the spleen was markedly enlarged. A number of rose-colored spots, which disappeared on pressure, could be seen. There was also a decided bradycardia, with a pulse of 40 to 52, which, despite cardiac stimulation, could not be brought up.

A blood smear was taken and sent to the laboratory for a Widal test. Although there was a slight diarrhœa present, occasional enemas were given to promote increased elimination of toxic products. An ice-pack was given at 2 P. M. which brought the temperature from 104.2° to 102.2°. At 8 P. M. the temperature was 103°. The ice-pack was repeated, and thus the temperature remained down until 8 A. M. the next morning.

October 28.—The Widal report from the laboratory was positive.

From November 7 the temperature gradually fell, and returned to normal on November 15. The albumin had then completely disappeared from the urine and the physical signs of the chest were entirely cleared up. The improvement of the general condition was now rapid and the patient was discharged on December 10, cured.

CASE II.—M. E., a nurse in the hospital, was brought to the wards for treatment on November 22, 1900. The history was as follows: For about two weeks she had been feeling languid and had had severe headaches. At various times a diarrhœa was present. She had had a number of chills followed by a rise of temperature.

The abdomen was distended, and there was gurgling in both iliac fossæ. The rose-colored spots, disappearing on pressure, were present. The spleen was enlarged. The temperature on admission was 103°, respiration, 16; pulse, 106. A specimen of blood was taken for a Widal test. A microscopical examination of it gave negative results.

November 21.—Temperature 8 A. M., 102°; 8 P. M., 103.4°. A sponge was given, and the temperature came down to 100.8°. Quinine in gr. v doses was given without any effect on the temperature. After four doses, there was cinchonism. Owing to the thready pulse, strychnine sulphate, gr. 1-30, every four hours was given. An enema of soap suds relieved some of the abdominal distention.

November 22.—Widal report from the laboratory is positive.

November 25.—At 3 o'clock P. M. the nurse in charge reported that the patient had a chill lasting fifteen minutes. A specimen of blood was taken, stained, and upon examination the typical tertian parasite was found. Quinine was now increased to gr. x doses.

November 28.—Temperature at 4 A. M. 103°. A sponge bath of alcohol and ice was given with no effect, the temperature going to 104°. At 12 M. the temperature was 103°. An ice-pack was given; at 3.30 the temperature was 101°, and at 6 P. M. 100.4°. There had been no chills since November 26.

To December 10 the temperature remained at about 101°. There had been no chills since November 26. The temperature remained at about 101°. Diarrhœa, with typhoid stools, was not as marked as earlier in the disease, but was still present.

December 13.—A diffuse, reddish rash was found, which covered the entire body. The nurse in charge said it had been present for a couple of days, but only in a few small patches. It was most prominent over the chest and back. The temperature rose slightly, and the patient felt bad. As there were no drugs given capable of producing this rash, a diagnosis of scarlet fever was made.

December 15.—Desquamation of a fine sort began to be pronounced. This fact confirmed the diagnosis. The temperature came down to normal, and the patient was discharged cured on December 29.

The presence of the tertian malarial plasmodia was confirmed on examination of the blood by Dr. William Moses at the hospital laboratory.

The presence of the Diazo and Widal reactions, the typical typhoid rose-colored spots, the beefy tongue, and the continuance of the fever after cinchonism and the disappearance of the plasmodia from the blood, were sufficient to make a positive diagnosis of typhoid fever. This diagnosis was made despite the fact that some authors claim that both malarial and typhoid fever cannot exist in the same person at the same time.

The therapeutic value of the ice-pack cannot be denied. It has been used most successfully in all our typhoid cases. The object of reporting upon the employment of the ice-pack in combating the high temperature in typhoid fever is to encourage its more general application in preference to the cumbersome Brandt method, which requires the presence of trained assistants and a minute knowledge of the method.

There is a positive slow reduction of the temperature after each application of the pack, which stimulates circulation and produces a marked tonic effect upon the general nervous system; in short, the application of the pack as an antifebrile measure has all the advantages of the Brandt method without any of its disadvantages. Adding the simplicity and ease of its application, it becomes an ideal measure in the hands of the general practitioner in meeting the symptom of hyperpyrexia and the disorders resulting therefrom.

ROUTINE DIGITAL EXAMINATION FOR CORD ABOUT THE NECK IN THE EXPULSION STAGE OF ALL HEAD-FIRST LABORS.

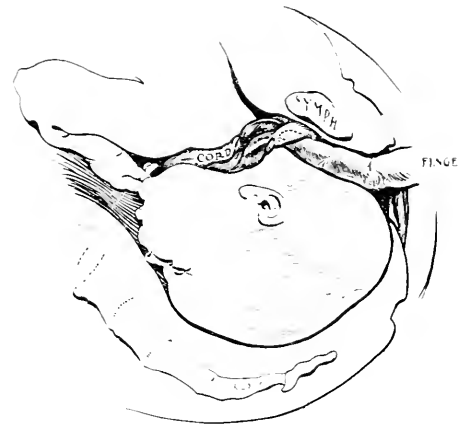
By ROBERT L. DICKINSON, M.D.,

NEW YORK.

ASS'T PROFESSOR OF OBSTETRICS, LONG ISLAND COLLEGE HOSPITAL; SURGEON TO BROOKLYN HOSPITAL; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY, ETC.

In every instance in which the head presents, it is desirable to determine whether the cord is about the neck or not. It is particularly necessary that one know whether there are two turns or more. The knowledge is worth having because it helps to decide whether the exit of the head may be long delayed to save the perineum, or whether expedition is necessary, and answers the question whether cyanosis of the scalp is a call for quick extraction. Although one turn of a long cord may produce no ill effects, a short cord may thus be drawn taut, and even a long cord may be so disposed as to produce oxygen hunger, with the bad results following premature respiration.

It is not always easy for the ear to determine what is the heart action of the fœtus at the time when the occiput is beginning to protrude. The focus of loudest sound is then behind or just above the pubic bone, not a comfortable place to apply the ear, particularly when the pains are stormy and frequent, or the muscles rigid, or the patient groaning, half under the anæsthetic between pains. Yet one must decide whether another twenty minutes can be stolen from the child's interest, for the sake of the integrity of the pelvic floor. Then the finger is passed in at the summit of the arch, between pains, and is kept there during a pain if the cord encircle the neck. The fetal pulse is accurately studied and the decision made. Before a low forceps application, one ought to know where the cord is. The dorsum of the finger is passed against the child's head, the tip hugging the occiput closely until the shoulder or nucha is reached. One finds a soft band about the neck always, and must determine whether it be the cervix or cord. Hooking the band gently forward toward the pubes, it is held against the back of the bone to feel whether it pulsates or not. If not, the finger hooks over the band



more actively and can tell the anterior lip from the navel string. The gentlest manipulation is always in order.

It is very common to find the pulsation of the cord slow down and stop during a pain, to be gradually resumed as the pain passes off; but as long as the intervals are adequate this momentary arrest of fetal heart action does not call for interference.

I have seen the cord four times about the neck, together with one-half hitch, and the child in as grave a case with a long cord once about the nape of the neck, but tied about both ankles as well. In many instances, with an average length of cord and a single turn, some unknown cause will check and stop the beat. A long symphysis, a short neck, an œdematous anterior lip, all may nip the cord.

On the Occurrence of Pulmonary Tuberculosis in Diabetic Subjects.—T. N. Kelynack gives statistics to prove that a large percentage of diabetic patients are attacked by pulmonary tuberculosis. The cause is obscure. It has been ascribed to the presence of the glucose having a favorable effect on bacterial growth, the sugar lowering the normal resistance of the tissue, and the diabetic cachexia and lessened alkalinity of the blood also assisting the tuberculous infection. Of nineteen cases of diabetes under the author's personal observation, pulmonary tuberculosis was found in eleven cases at autopsy. Even in the non-tuberculous cases pulmonary congestion and œdema or bronchitis were usually present. As far as may be, a non-tuberculous environment should be sought for diabetic patients.—*Medical Press and Circular.*

Society Reports.

THE MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Thirty-fifth Annual Meeting, Held at Deal Beach, N. J., June 25, 26, and 27, 1901.

First Day—Tuesday, June 25

The meeting was held at the Hathaway Inn, and was called to order by the First Vice-President, Dr. John D. McGill, of Jersey City, who occupied the Chair vacated by the death of the President, Dr. William Pierson, of Orange.

The Secretary reported that at the birth of the Society, one hundred and thirty-five years ago, the membership had been only seventeen, it was now nine hundred and eighty-four.

The Medico-Legal Expert.—Dr. John D. McGill took this as the theme of the annual address. He said that the successful medico-legal expert must not only be erudite, but must possess certain physical and psychological qualities. The distinction was drawn between opinion evidence and true expert evidence. The former was apt to be founded on impulse or prejudice. The competency of the expert witness must be decided within the discretion of the Court, and could not be left to the jury. A general practitioner might testify upon any question of medical science, but if one qualified as a specialist he could only give evidence connected with that special department. The consulting physician must base his opinion upon what he himself has discovered in the case, and not upon the history and other facts furnished him by the attending physician or the nurse. While the subjective symptomatology should be given due weight, the expert opinion should be based chiefly upon the objective symptoms. It was well to remember that if a true subjective symptomatology had existed for a considerable length of time it would usually lead to the development of a more or less distinct objective symptomatology.

Report of the Standing Committee.—Dr. H. W. Elmer, of Bridgeton, Chairman of this Committee, presented the report. He stated that ten counties had furnished reports, and these showed that last winter and spring had been characterized by more than the usual amount of sickness, particularly of influenza and pneumonia. The reporter of Mercer County reported that large doses of the salicylates had seemed to be capable of aborting many cases of pneumonia, and that this treatment was certainly well worth a more extended trial. Scarlet fever had been prevalent throughout the State. The outbreaks of smallpox had served to show the efficiency of the health authorities, and the extent to which vaccination had been neglected in recent years.

Progress in Surgery.—Dr. Charles Young, of Newark, read a portion only of this report. He said that experience with intraspinal cocainization seemed to show that there was generally less shock after operations in which it had been used, and that it was the method of choice for operation on the lower two-thirds of the body. It was not well suited to children, nor for the majority of operations of intraperitoneal surgery. Fourteen cases had been reported in which the new operation for cirrhosis of the liver, i. e. the opening up of a new channel for the circulation, had been done. Mention was made of the work of Dr. George R. Fowler in connection with the operation which he calls "decortication of the lung," for chronic empyema. His first operation was done in October, 1895, and since that time he had been able to collect thirty cases. Of this number eleven patients had been cured and six improved, while nine had remained unimproved. His conclusions were (1) it may be advantageously substituted for Estlander's operation in the majority of instances; (2) it should replace Schede's operation in all cases; (3) the method of evacuation of the diseased pleural sac bears as the operation of choice; (4) failing in this, visceral pleurectomy should be selected; (5) pleurotomy, with simple detachment of the diseased pleura, gives sufficiently good results to warrant a surgeon in resorting to it when the condition of the patient will not permit of other procedures, and (6) pulmonary or respiratory exercises should not be neglected in the after-treatment.

Diseases of the Nose and Throat.—Dr. B. A. Waddington presented this communication based upon his thirty-six years' experience as a general practitioner, directing special attention to the baneful results of the infectious diseases.

Progress in Bacteriology.—Dr. D. H. Bergey, of Philadelphia, read this report. In it he dwelt particularly on the progress made in two fields. One of these was the study of the internal structure of bacteria. The "polar granules," he said, had been found to be dependent upon the character of the nutrition of the cells, and to be made up of a special variety of protoplasm. An investigation in the laboratory in Philadelphia on the so-called branched forms of the diphtheria bacillus seemed to show that these forms cannot be classed as mycelial. The other field considered was that of applied bacteriology. Ehrlich and Morgenroth had investigated the process of hæmolysis or the solution of the red blood corpuscles in the body. Ehrlich tried to place the immunizing process upon a chemical basis known as his "side-chain theory." Work had also been done regarding the nature of the agglutination reaction. Reference was also made to the recent experience of the English army in South Africa with inoculations in the prevention of typhoid fever, and the statement was made that, while no statistics were yet at hand, there was reason to believe that this method had afforded striking protection to the nurses engaged in taking care of soldiers sick with typhoid fever.

Second Day—Wednesday, June 26.

What Measures are Practicable for Preventing the Spread of Tuberculosis?—Dr. HENRY MITCHELL, of Asbury, the third Vice-President, presented an essay on this topic. He said that the pasteurization of milk had probably led to the saving of many lives which would have otherwise been lost by infection with tuberculosis. The mortality from all tuberculous affections had been greatly diminishing in the State of New Jersey, and the same was true of every other state in this country, and also of the countries throughout Europe. This reduction in the mortality must be credited to the work of the older sanitarians. Tuberculosis rarely spreads where water, air, and soil are free from pollution and there is a free access of sunlight. In New Jersey during the past twenty-two years the death rate from tuberculosis had been reduced from 0.53 to 1.10 per ten thousand inhabitants. Consumption is everywhere regarded as a preventable disease. Those who are now suffering from it are entitled to much more sympathy and forbearance than will those who subsequently become its victims. The Legislature of New Jersey in 1900 enacted a law opening the way for education in the public schools on personal hygiene, particularly as regards this dread scourge. The chief administrative measures advocated by the essayist were: (1) A general application of the principles of hygiene; (2) the prevention of the sale of contaminated milk; (3) the distribution of printed instructions to consumptives; (4) ordinances prohibiting expectoration on the streets; (5) house to house inspection to locate infected apartments; (6) regular periodical inspections of schools; (7) voluntary notification by physicians of cases of tuberculosis and a proper oversight adapted to the individual case, and (8) under certain circumstances, isolation. No one could guarantee that a public record could be kept private, hence the suggestion that the [illegible] of tuberculosis should be

private was not practicable. It had been found in a large series of cases of autopsies that evidences of past or present tuberculosis existed in 97 per cent. of persons dying between the eighteenth and thirtieth years of life. The essayist was of the opinion that very little had been accomplished by notification of health authorities regarding this disease, and he thought this foe of humanity could be effectively combated only by attacking it in advance of its development.

Arteriosclerosis and the Nervous System.—Dr CHARLES LEWIS ALLEN, of Trenton, read this paper. He said that the nerves have a very rich blood supply, always from more than one vessel. The spinal cord is supplied both from the anterior and the posterior spinal arteries. All the vessels entering the cord are end arteries and do not anastomose, so that if one of these became plugged the area supplied by it must suffer. Attention was directed to cases of intermittent limping occurring not infrequently in young persons, and almost certainly dependent upon sclerosis of the vessels of the foot. The diagnosis of arteriosclerosis of the nervous system was to be made by the general symptoms and the occurrence of arteriosclerosis elsewhere. The long-continued use of potassium iodide in small doses was undoubtedly beneficial when combined with proper hygienic measures.

Dr. E. W. HEDGES, of Plainfield, said that history showed that in olden times, when man lived almost wholly on nuts and fruits, he lived to be several hundred years old, and that as his dietary became enlarged the span of life was steadily reduced. This was notably the case after the cereals had been added to man's food. According to Thompson, if we would prevent arteriosclerosis we should eat more of fruits and nuts and less of the cereals. Another cause of atheroma was to be found in overeating, a fact that had been well brought out by a physician who, from a study of the life habits of one thousand people who had attained the age of one hundred years, discovered that the only thing these persons had in common was a tendency to temperate eating.

Dr. RYERSON, of Boonton, said that he had long been interested in this subject, and he had reason to believe that old age and atheroma were dependent upon a faulty elimination of the phosphates. He had long wrestled with the problem how to increase their elimination, and while far from having arrived at a satisfactory solution he wished to call attention to the property lactose possesses of doing this. He had previously read a paper on this topic before this Society, and would now only say that he had found that on an average it increased the elimination of the phosphates about 50 per cent. and that with this increased elimination many persons showed a corresponding improvement in their symptoms.

Infant Feeding, Some Difficulties in the Management of those Deprived of Milk.—Dr ALEXANDER MCALLISTER of Camden, was the author of this essay. He said that the regular weighing of infants at short intervals afforded the most reliable guide to the effect of the food upon the infant. A distinction should be made between fatness and robustness. The home modification of milk is useful, but there is still a need for an easy and generally applicable working formula. There is a mistaken, though very prevalent, notion that almost any one can minister to a bottle-fed child.

Some Observations on the New Hæmostatic Adrenalin.—Dr. N. L. WILSON, of Elizabeth, presented this communication. He said that the basic substance of the suprarenal extract oxidized so rapidly that it had been desirable to make a chloride of it. In the tablet form the active principle of this gland is made up as a tartrate of adrenalin. In the liquid form contamination soon occurs, especially if the dropper is frequently introduced into the solution, but it can be sterilized by heat. The tablets are useful because they are very convenient for the extemporaneous preparation of the solution. It was at the writer's suggestion that this active principle had been named adrenalin. When this substance is dropped into the eye there is moderate smarting and a state of hyperæmia is produced which lasts for about twenty seconds, and is followed by a marked blanching of the conjunctiva. There is apparently no stimulation of the sympathetic nerve. It has no bad effect on the conjunctiva, and when used in connection with cocaine or holocaine augments the anæsthesia produced by these substances. When applied to the mucous membrane of the nose, adrenalin causes a marked blanching. It is also useful for examinations of the naso-pharynx. For the temporary relief of hay fever it has no equal. Every operation about the nose can be made bloodless or nearly so by application of adrenalin, but it should be remembered that in about one hour after the operation there will be bleeding, though no more than there would have been during the operation had no adrenalin been used. In order to control such hemorrhage the patient should be given a 1 to 1,000 solution of adrenalin and told to use it for two days. So far as known, adrenalin has done no harm when freely used. Mention was made of a case in which adrenalin had been administered to a pregnant woman having hemorrhages from the nose and from the gums. These had been checked, and then her attending physician, being fearful of the occurrence of postpartum hemorrhage, had kept up the adrenalin until after her confinement. Parturition had occurred normally. She took in the last three weeks of pregnancy five ounces of the solution of adrenalin.

Dr. W. B. JOHNSON, of Paterson, said that he had made considerable use of suprarenal extract and of adrenalin, and he thought the former was just as effective but it was dirty and unstable. He thought he had been able in a number of instances to prevent the development of a suppurative otitis by spraying adrenalin solution in the vicinity of the Eustachian tube. His theory was that when there was an accumulation of serum in the middle ear by reason of the imperviousness of the Eustachian tube, it was possible by the application of adrenalin to the orifice of this tube to reduce the congestion and allow of the escape of the serum.

Dr. ROGERS, of Paterson, suggested that adrenalin might prove useful in relieving œdema of the glottis.

Dr. CHARLES J. KIPP, of Newark, said that he had made daily use of adrenalin for many months and could endorse what had been said regarding it by the reader of the paper. The solution soon becomes cloudy after opening the bottle, and it had seemed to him that sterilization by boiling impaired its efficiency. He could not understand how the remedy could act in the manner described by Dr. Johnson unless it were injected through the whole length of the Eustachian tube. Its place in eye disease was chiefly that of a cosmetic. Thus, in a case of bad conjunctivitis its repeated application would make the patient look quite presentable, but that was about all that could be said for it. Adrenalin sometimes assisted the physician in differentiating between conjunctivitis and iritis. If iritis was present the deep congestion of the ciliary vessels would persist after the application of the adrenalin.

Neuralgia and Allied Affections.—Dr. WILLIAM M. LESZYNSKY, of New York, read a paper with this title. He said that from our present knowledge neuralgia must be considered to be the result of some alteration in the nutrition of the nerve structure itself resulting from interference with its vascular supply. It was almost wholly confined to adult life. The trigeminus and its branches furnished more neuralgias than any other nerve. Pain in the course of both sciatic nerves should at once lead to the suspicion of disease of the spinal cord or of the posterior roots. Many cases of so-called intercostal neuralgia were now known to be examples of neuritis. Peripheral neuritis was usually accompanied by pain on

slight pressure over the whole course of the nerve trunk. The successful medical treatment of neuralgia implied a definite knowledge of the condition, the keeping of a distinct object in view, and careful attention to details. The use of irritating or anodyne applications to the face was usually of little avail, and often did harm. Attention to the general health, and the frequent use of the galvanic current would ordinarily prove beneficial. In some cases of lumbo-abdominal and sciatic neuralgia great relief followed prolonged hot rectal irrigations. Nerve section should never be considered seriously until careful systematic treatment had been persevered in for a long time. While the danger of establishing the morphine habit in neuralgics had been greatly exaggerated, it should always be borne in mind. For its occurrence the physician was often responsible by having taught the patient or some member of the family the use of the hypodermic syringe.

A Plea for the Physician on the Witness Stand.—Dr. DANIEL STROCK, of Camden, read an essay with this title. He pointed to the fact that it was not a personal matter, but a provision of law, that the lawyer cannot divulge the communications of his clients, and he held it to be unfair that the same protection was not afforded to physicians in their relations with their patients. The code of medical ethics, the moral and business guide of the physician, had no support in legal enactment. It was evident, therefore, that in the State of New Jersey, and indeed wherever the courts are governed by the common law, the medical witness is wholly at the mercy of the lawyers and can receive no protection from the Court, except in those rare instances in which the Court intervenes on the broad ground of public policy. If in the direct examination, even in courts where the physician is protected in the matter of disclosing communications from his patients, the physician has partly disclosed the condition of the patient, he may be compelled on cross-examination to give the full details bearing upon what he has already partly testified to. The essayist said that there was reason to believe that the judiciary generally would be glad to have the physician fully protected regarding the communications made to him by his patients, and it therefore remained for the medical profession to take the initiative in securing this important reform.

Dr. THOMAS W. HARVEY, of Orange, spoke of another phase of this subject, namely, the revealing of information received from patients by the act of filling out the proofs of death required by life insurance companies. In application for life insurance a waiver is often inserted which empowers the applicant's physician to disclose the nature of the previous illnesses of the applicant. For that particular purpose such a waiver may be all right, but it does not apply after the death of the individual.

Dr. CHAVANNE, of Salem, earnestly urged the Society to at once take whatever steps were necessary to secure proper representation before the Legislature and the enactment of law which would afford physicians protection in the matter under discussion. The question was referred to the Committee on Legislation, with the request that it make a report at the next annual meeting.

The Modern Treatment of Gonorrhœa and its Complications.—Dr. DANIEL CURRIE, of Englewood, presented this essay. He said that a saturated solution of methylene blue in alcohol was an excellent stain for gonococci. Until the gonococci had been banished no cure was possible. As a two per cent. solution of protargol would cause a disappearance of the gonococci for twenty-four hours or more he had not found it necessary to use injections of this substance oftener than once in twenty-four hours. Plain hot water was irritating to the urethra. When the posterior urethra became affected one pint of a one per cent. solution of protargol should be used for the irrigation of the urethra. After the germs had disappeared the injections of mild solutions of zinc and copper were in order, and salol should be given internally. When the spermatic cord became involved, the testicles should be at once suspended, all urethral treatment stopped, and the patient instructed to keep recumbent. Much conjugal infelicity might be avoided if the physician would take the precaution to have specimens of a suspected discharge examined microscopically and cultures made from it.

Dr. E. B. SILVERS, of Rahway, spoke of the serious results flowing from the joking way in which too many physicians treat patients suffering from "only the clap." Surely it was no cause for jest, when a man had a disease which might lead to the gravest disorders not only in himself but in his wife and children. It had been the lot of the speaker to see many cases of urethral stricture, and he declared most positively that in simple non-inflammatory strictures he knew of no treatment superior to electrolysis. Those who had opposed this treatment had failed because they had not selected the right kind of cases.

Dr. M. LAMPSON, of Jersey City, that if one wanted a familiar and practice example of the progress that had been made in medicine in the last twenty-five years one had only to note the great changes that had been made in the treatment of gonorrhœa, due to our increased knowledge concerning the nature of this affection. We had learned that the late Dr. Noeggerath had not been so far out of the way when he had declared that almost all woman's ills were traceable to the ravages of gonorrhœa. The speaker had operated upon over one hundred cases of urethral stricture, and could not recall a single one that had not been the result of gonorrhœa.

Dr. CHAVANNE, of Salem, rather tersely summed up what he considered the proper treatment of urethral stricture, *i. e.* by the use of sounds, in the recommendation to use "cold steel."

The Treatment of Neurasthenia.—Dr. W. B. STEWART, of Atlantic City, was the author of this essay. He said that the first requisite was to exclude hysteria and insanity, and recognize neurasthenia as a functional disorder dependent upon something causing spinal irritation. This cause should be sought for by an exhaustive study and removed if possible. It was absolutely necessary to gain the full confidence of the patient at the outset; hence the physician should not give his opinion until after having thoroughly studied the case. He should always be sympathetic, firm, and strictly methodical, and should take time to allay the mental excitement and morbid fears of the patient. These talks with the physician should be given with the same regularity as the medicine. A system of mental education must be begun, and must be continued until the physician's personality overbalanced that of the patient. The examinations should always be made carefully and deliberately, and in the presence of another person. Lithæmia and anæmia were important etiological factors, though the speaker's own experience pointed strongly to dietetic conditions as being most commonly responsible for the neurasthenia. It should be made an invariable rule to look to the diet and digestion. All sweets, fried and rich foods, desserts, and strong tea and coffee should be forbidden. Liquids should not be taken during the act of mastication. Neurasthenic subjects assimilate their food imperfectly, though presenting a healthy appearance to the superficial observer. Constipation must be combated vigorously by the use of massage, suppositories, occasional enemata, and change of diet. The physician would find the most trouble in treating sexual perverts. The average neurasthenic never knew when to stop; some did not know when to start. If the patient were a nervous worn-out society woman, an absolute rest cure for several weeks was indicated. Very few men would stand this treatment; some women would. The modified treatment was more generally applicable

Too many neurasthenics had acquired the lazy habit and should be encouraged to walk and take moderate exercise, and live on plain substantial food. Massage and electricity were valuable adjuvants, but should always be given with discrimination. The method and time of application must be carefully determined. Cool or cold sponge baths in the morning, followed by a rub with oil or alcohol, were often beneficial. Hot baths should not be used. A rest of one or two hours should always be taken after a bath. Insomnia and the drug habit were two prominent features which must be met. The physician must not be too radical at first, but should at once impress the patient with his firm determination to cut away from drugs as soon as possible. Nerve storms, sinking spells, and mental depression were common accompaniments of the constant taking of sleeping drugs such as sulphonal and trional. The physician should be most scrupulous about not administering any of these remedies regularly and systematically, and should never tell the patient the name of the drug. Their action would be better if the physician would carefully outline in advance what action was to be expected from them.

Dr. PHILIP MARVEL, of Atlantic City, classified neurasthenia as follows: (1) Neurasthenia from exhaustion, *e. g.* in the overworked broker or banker; (2) neurasthenia from hyperexcitability, *e. g.* in persons who have received a shock or fright; (3) neurasthenia from toxæmia, *e. g.* cases of autotoxæmia, and (4) neurasthenia arising from traumatism. The selection of the method of treatment was all-important. Thus, it would be manifestly improper to select for the rest cure a highly excitable person, whereas neurasthenics showing great exhaustion would be benefited by such treatment. The toxæmic cases required treatment of the gastrointestinal tract. Massage tended to relax the vascular tension so noticeable in most of these cases. The speaker's main reliance was upon the proper use of baths, massage, and electricity.

Dr. G. H. BALLERAY, of Paterson, said that he was inclined to think that every one was more or less neurasthenic, just as it had been said that every one is more or less crazy; it is chiefly a question of degree. Neurasthenia was a matter of heredity and environment, and the patient must not be made to fit the treatment, but the latter be adapted to the patient. Prophylaxis was, of course, of the first importance. Neurasthenia in women was often associated with menstrual disturbances, or with the debility arising from child-bearing and lactation.

Some of the Infections, Their Genesis, Habit, Consequences, and Prevention.—Dr. SAMUEL E. ARMSTRONG, of Rutherford, read this paper. The author considered especially abscess, syphilis, and malaria, and laid great stress on the necessity for the State of New Jersey taking immediate steps for destroying mosquitos in order effectively to combat malaria. He hoped a committee, consisting of representatives from each county, would be appointed to consider the best means of attacking this problem in the State of New Jersey.

Dr. FERDINAND M. JEFFRIES, of New York, said that the problem of reaching the Legislature effectively was a difficult one, but a hint was afforded by certain legislation in the West. For example, the collection of the noxious loco weed had been encouraged and the state had bought it at a fixed rate per ton. Again, in order to do away with a thistle that had injured the hay crops a law had been passed in Washington compelling each land owner to cut down the thistles before they went to seed. A similar law, compelling land owners to fill in or properly attend to breeding places for mosquitos would be in the right direction and would be a power for good. Certain communities in New Jersey had already done something in this direction without waiting for state legislation.

Dr. ALEXANDER MARCY, of Riverton, said that he had certainly seen some striking examples of malarial infection occurring in a portion of the State where there are practically no mosquitos, and he was disposed to believe that the mosquito was only one of the means of conveying the malarial plasmodium to the human being. He mentioned that in a number of cases of severe malaria in which quinine alone had appeared to be almost useless, the disease had been most satisfactorily controlled by administering methylene blue in conjunction with the quinine.

Diagnosis of Intestinal Perforation in Typhoid Fever.—Dr. JOSEPH STOKES, of Moorestown, presented this paper. He said that only within the last few years had it been known that the perforation actually takes place some hours before the appearance of the usual symptoms given for this condition, viz., sudden abdominal pain, collapse, general abdominal tenderness and rigidity, and the peculiar expression of the face. Perhaps the most important of the early symptoms was pain, which was rarely absent. Its onset was usually sudden, and it was generally, though not always, severe. In a large proportion of cases the pain was located in the right ileocæcal region. Another early symptom, and one almost invariably associated with abdominal pain, was rigidity of the abdominal muscles. The occurrence of these two symptoms together in the third week of typhoid fever was almost pathognomonic. Another symptom which was fast assuming some importance was leucocytosis. This was usually so transient, however, that to be of any value counts would have to be made daily, indeed almost hourly, by experts. Immediately after perforation there was little to be learned from either the pulse or the temperature. Nausea and vomiting were early symptoms in only a small proportion of cases. The object of the paper was to disabuse the medical mind of the notion that intestinal perforation in typhoid fever was characterized by a sudden and overwhelming change in the patient.

Dr. ALEXANDER MARCY, of Riverton, said that it was far better to operate in a case of suspected perforation when one does not exist than to let a patient one die in a case in which perforation has not been suspected.

Dr. LOUIS FAUGÈRES BISHOP, of New York, said that when a person is sick and is suffering more or less all the time the onset of perforation might be very easily overlooked. The physician should be constantly on the alert during the course of typhoid fever for that particular form of rigidity of the muscles which affects one side of the abdomen more than the other, and when such rigidity was detected its warning should not be disregarded.

Dr. PHILIP MARVEL, of Atlantic City, while admitting the inconveniences and difficulties associated with making blood counts, insisted that the making of the leucocyte count in typhoid fever was well worth all the trouble expended upon it. Even if such examination led to error in diagnosis, this error would be on the safe side for the patient, and it might afford valuable information as to the existence of a peritonitis or an appendicitis.

Third Day—Thursday, June 27.

The Proper Temperature for Ear Douching.—Dr. TALBOT R. CHAMBERS, of Jersey City, presented a brief communication on this subject. He reiterated his belief in the value of an ear douche at a temperature between 120° and 130° F., and exhibited the apparatus which made the use of such a high temperature possible. A two-quart fountain syringe, a bath thermometer, and a glass or hard-rubber douche apparatus for insertion in the external auditory canal were all the requisites.

Ethyl Bromide, A Primary Anæsthetic before the use of Ether or Chloroform.—Dr. EMERY MARVEL, of Atlantic City, read this paper. The author's method had been for the anæsthetizer to enclose a piece of gauze in the palm of the hand and pour upon the gauze one fluid drachm of ethyl bromide, exceptionally a larger

quantity. The patient was usually unconscious in forty to forty-two seconds, and then either chloroform or ether was substituted. Full anæsthesia was usually induced in about three minutes. By this method excitement, coughing, and excessive bronchial secretion had been avoided. No unfavorable action on the heart or on respiration had been observed. The tendencey to vomit after chloroform or ether could be reduced but not altogether removed by the prior use of ethyl bromide. The author stated that the advantage of this method when chloroform was employed was slight, but it was very marked when ether was used.

Remarks on the Diagnosis and Treatment of Early Ectopic Pregnancy.—Dr. G. H. BALLERAY, of Paterson, was the author of this paper. He said that the frequency of ectopic pregnancy might be inferred from the fact that since February of the present year he had seen seven such cases. While it was true that ectopic gestation was more common among previously sterile women, sterility should not be taken into consideration in making the diagnosis. The typical symptoms were amenorrhœa, followed by an irregular discharge of blood from the vagina, the occurrence of colicky pain in the lower part of the abdomen, and occasionally the discharge of pieces of decidua. The softening of the cervix, so marked in normal pregnancy, was not commonly a prominent sign in ectopic pregnany. The changes in the breast characteristic of pregnancy were not always present. When there was a reasonable doubt, the bladder and rectum should be thoroughly emptied and an examination made under general anæsthesia. In true hæmatosalpinx the symptoms of pregnancy were absent. When there had been a rupture into the folds of the broad ligament there was less shock than when the product of conception was effused into the general peritoneal cavity, and it was followed by a characteristic bearing-down sensation. The treatment of extrauterine pregnancy should be purely surgical, and all other methods should be condemned. In cases of hæmatoma of the broad ligament, the interests of the patient would be best conserved by leaving her alone, for it would generally be found that if this were done she would recover within a few weeks and that almost no signs of the hæmatoma would be left. He considered abdominal section, and not operation by the pelvic route, the proper procedure in cases of ectopic pregnancy. When the hemorrhage was still going on operation through the vagina would be tempting Providence, and trifling with human life.

Dr. P. A. HARRIS, of Paterson, advised the complete ignoring of the descriptions of ectopic gestation published a few years ago. He thought that in over half of his cases of ectopic gestation seen in recent years there had been no sudden increase in the pulse rate, the pulse having been on an average about 85. Moreover, he thought the diagnosis should generally be made before the occurrence of that quickening of the pulse which figured so prominently in the older descriptions of this condition. In very early cases of ruptured tubal abortion there was usually profuse hemorrhage, with severe pain and a rapid pulse, without previous symptoms. When rupture occurred later, the pain was usually less intense and hemorrhage was not so copious. If a woman who had previously menstruated regularly went beyond her time for five to seven days, and then had some pain and an irregular flow of blood, the physician should at once suspect ectopic pregnancy.

Report of a Case of Tumor of the Neck.—Dr. J. C. MCCOY, of Paterson, reported this case, the prominent features of which were very rapid emaciation, some dyspnœa, undue prominence of the eyes, and the presence, of a lobulated tumor of the neck, moving during the act of swallowing. The origin of the growth was probably in the thyroid, and while, histologically, the structure suggested an adenocarcinoma, the macroscopical and clinical appearances were those of a fibroma. He had extirpated the growth, and the patient had recovered in three weeks.

Report of a Case of Suppurative Choroiditis.—Dr. T. R. CHAMBERS, of Jersey City, reported this case chiefly because it had followed a course just the reverse of that usually described.

Suggestions Regarding State Aid for Hospitals.—Dr. W. B. JOHNSON, of Paterson, read this paper. His position was commended by Drs. E. Marcel and Chavanne.

A Case of Cæsarian Section for Deformity of the Utero-vaginal Canal.—Dr. G. H. BALLERAY, of Paterson, in reporting this case, mentioned incidentally the inadvisability of using the rubber ligature because it causes atrophy of the lower uterine segment. It was better, he said, to have the vessels controlled by a trustworthy assistant.

Discussion on What Reliance Can Be Placed upon the Image Produced by the X-Ray from a Medico-Legal Standpoint.—Dr. CHARLES L. LEONARD, of Philadelphia, opened the discussion. He said that while the nature of the *x*-rays was not known, the laws of physics governing them were well understood. This method could be employed satisfactorily as a means of diagnosis only by the medical profession, and those especially trained in the use of this new diagnostic method; it was not to be expected that it could be used with advantage by the laity. The treatment of cases of suspected fracture as if a fracture really existed was not good surgery at the present time, and was not necessary with *x*-ray examinations at our disposal. It was not advisable to employ the Roentgen ray for the diagnosis of fracture to the exclusion of other methods, but all reliable means of diagnosis should be used. The value and accuracy of the Roentgen ray for medico-legal purposes were entirely dependent upon the skill of the expert using this method. It was necessarily opinion evidence, but was founded upon tangible data. The knowledge of normal and pathological anatomy, as disclosed by the *x*-ray, was presupposed to exist in one essaying to employ this method for diagnosis. It should be remembered that the Roentgen method does not recognize the injury that has been done to the soft structures. It often demonstrates the impossibility of securing proper apposition of the fragments without an operation. A skiagraph showing the cancellated structure of the bone should enable an expert in *x*-ray work to detect a fracture if one were present. The determination of non-union of a fracture was not possible by the use of the *x*-ray unless the fragments were separated or unless two skiagraphs were taken showing different aspects of the part. The identity of a picture could be established by using lead letters under the limb. If a skiagraphic plate were written upon with ink, as for example signed by the person making the skiagraph, it would be impossible to manipulate the plate, except locally, without destruction, for the ink would run and stain the plate. Whenever a skiagraph was introduced in evidence an expert opinion should be secured from both sides to a suit. In charges of malpractice it was not the beauty of the bone scar that should be considered, but the clinical result. Neither lawyer, photographer, nor professional witness without special experience was capable of correctly interpreting a skiagraph, nor was he competent to give testimony thereon.

Dr. CARL BECK, of New York, continued the discussion. He asserted that, aside from the discovery of aseptic surgery, the discovery of the Roentgen rays was greater than any other of its kind in the century just past. Surgeons sometimes seemed to be either jealous or fearful of this new ally. It was true that the Roentgen rays could reveal the surgeon's mistakes, but they also showed the limitations of the best surgical skill, and often proved conclusively that the surgeon had done the very best possible for a given case, though the patient was not satisfied. These rays do not take cognizance of tro-

phoneurotic disturbances, and hence might show the bones in excellent condition, although the person injured might be justly entitled to indemnity. It was impossible to diagnose a fracture of the base of the skull by means of the *x*-ray. Dr. Beck then exhibited a series of skiagraphs, emphasizing the points made and showing the possibilities of this method. He predicted that an *x*-ray apparatus would in time become as necessary a part of the general practitioner's outfit as was the microscope now.

Dr. Leonard, in closing, made some remarks on the value of the *x*-rays in detecting ureteral calculi.

Officers and Place of Meeting.—Dr. John D. McGill, of Jersey City, *President*; Drs. E. L. B. Godfrey, of Camden; Henry Mitchell, of Asbury Park, and A. W. Taylor, of Beverley, *Vice-Presidents;* Dr. E. W. Hedges, of Plainfield, *Corresponding Secretary;* Dr. W. J. Chandler, of South Orange, *Recording Secretary;* Dr. A. Mercer, of Newark, *Treasurer*. The next meeting will be at Atlantic City on June 24, 25, and 26, 1902.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, held May 23, 1901.

A. BROTHERS, M.D., CHAIRMAN.

Pan-Hysterectomy.—Dr. CHARLES N. DIXON JONES presented the patient upon whom the first pan-hysterectomy had been done in America, together with the specimen removed at that operation. The operation had been done thirteen years ago.

Hydrosalpinx.—Dr. G. H. BALLERAY presented a specimen of hydrosalpinx, and in that connection said that although he had operated between two hundred and three hundred times for pyosalpinx, this was the first hydrosalpinx that he had encountered.

Ectopic Gestation.—Dr. BALLERAY also presented a fœtus, with the decidua, which was a complete cast taken from a case of extra-uterine pregnancy. He had operated per vaginam, and had met with such profuse hemorrhage that he had been almost tempted to open the abdomen in order to control it. The hemorrhage had been finally controlled by packing. He could not understand any one advising vaginal section in cases in which there was hemorrhage into the general peritoneal cavity.

Echinococcus Cysts of the Mesentery.—Dr. BALLERAY also presented this specimen, which had been removed from a patient who had had the tumor for about twenty years. Four colleagues had examined the case and each one had made a different diagnosis. All of the tumors were adherent. The diagnosis of echinococcus cyst had been confirmed by the finding of the characteristic hooklets under the microscope.

Large Ovarian Tumor.—Dr. H. J. BOLDT presented a large ovarian tumor which had existed for a number of years, and which, on removal, appeared to be colloid.

Ectopic Pregnancy.—Dr. PAUL F. MUNDÉ presented specimens from two cases of ectopic pregnancy, one of them a tubal abortion. Because of the sudden sharp pain and rapid collapse and the symptoms of gradual internal hemorrhage, he had been able to make the diagnosis of tubal abortion in this instance before operating. Mention was made of another case, seen about the same time both by himself and a colleague. Both of them had agreed on the diagnosis of ruptured ectopic gestation, but as the rupture was intraligamentous and the hemorrhage had ceased, Dr. Mundé had not insisted on operation, and after two weeks the large mass had been absorbed.

Rapid Reduction of a Fibroma.—Dr. PHILANDER A. HARRIS presented a uterus removed three months ago from a woman, thirty-five years of age, who had never had children. When first seen by him, last August, there had been an abdominal tumor reaching up to the umbilicus. Upon palpation, it appeared to be a fibroma. He had not seen her again until January, and had then been surprised at the tumor being very much smaller. The patient stated that shortly after he had seen her last summer the tumor had rapidly diminished to about half its former size. As there was reason to suspect pregnancy, when the woman was seen in January, he had made a suprapubic incision for the purpose of exploration, after a consultation with Dr. Coe. The uterus, tumor, and gestation sac were removed.

Abscess of the Broad Ligament: Calcareous Concretions in the Ovary.—Dr. A. ERNEST GALLANT presented this specimen.

The Palliative Treatment of Fibroids.—Dr. H. C. COE read this paper. He said that when there was a small subperitoneal or even an interstitial fibroid tumor and an entire absence of symptoms, no conservative physician would be willing to advise operation. Sometimes a tumor apparently insignificant in size might assume great importance because of its position or its association with pregnancy. The important symptoms in connection with fibroids were hemorrhage, pain, and pressure symptoms. One must carefully consider the amount of the hemorrhage and its effect upon the individual. He was in the habit of insisting upon seeing the patient at the height of the hemorrhage, and noting the effect of the loss of blood upon her at the time as well as the rapidity with which she recovered from it. In the palliative treatment of such a case a good deal could be accomplished by regulating the diet and habits of life, supporting the uterus perhaps with a pessary, and warning aganist anything which tended to increase pelvic congestion. Because of the liability to pelvic congestion from sexual intercourse, the marriage of such a woman was risky. It was his own practice not to give ergot during the height of the menorrhagia, but in small doses, combined with strychnine or hydrastin, he used it in the intermenstrual periods. During the hemorrhage, the patient should be kept absolutely quiet in bed for the whole menstrual period. Complete rest in bed, with the foot of the bed raised would sometimes be sufficient to check the hemorrhage. Sometimes prolonged hot douches, with or without a styptic, like alum, were useful, but this beneficial effect was far from being the rule. In many of these cases, especially where there were interstitial fibroids, the uterine canal was so tortuous that it could not be tamponed easily without preliminary dilatation, a procedure that was far from safe. It was very common for practitioners to insert two or three balls of cotton into the vagina, and think that this constituted an effective tampon for the control of hemorrhage, but if done in this way, the tamponade was utterly useless for such a purpose. An efficient tampon for the control of hemorrhage was made by placing the patient in the knee-chest position, introducing a large-sized Sims speculum, and then systematically filling the vagina with a large number of small pieces of non-absorbent cotton. It was no exaggeration to say that in making such a tampon it was not unusual to introduce nearly a hand-basin full of such pieces of cotton. Of course such a tampon was very uncomfortable to the patient and it was often necessary to empty her bladder by catheter while the tampon remained. Regarding the use of electricity, the speaker said that he looked upon it as purely symptomatic in its effect, and thought the method should only be employed by an expert in this work. Aseptic curettage, followed by swabbing out of the uterus with carbolic acid, and then with alcohol, was sometimes a very useful means of checking hemorrhage, and this good result might last for years. He had never seen any bad results from such curetting in cases in which

the only symptom of importance was hemorrhage. Ligation of the uterine arteries did not seem to him rational, or a procedure which would give permanent relief. Personally, this method had given him no results at all. When the tumors are packed tightly in the pelvis, thus causing severe pain, it might be well to give an anæsthetic, push the tumors up and introduce a pessary. Pressure symptoms could sometimes be relieved by an abdominal bandage. Every case of fibroid should be seen by the physician about once in six months. He believed that a patient with a small fibroid nodule in the uterus should not be told of the presence of th tumor, as this would be useless and needlessly cruel.

Fibroids Complicating Pregnancy—Dr. CHARLES JEWETT reported three cases of this kind. In the first, the tumor was broadly sessile, and the woman was delivered by cæsarean section. She died thirty-six hours afterward from exhaustion. In the second case, cæsarean section, followed by hysterectomy, was done, and both mother and child did well. The third patient had been seen while suffering from a fever believed to be septic in character. Hysterectomy had been performed immediately, and the patient had left the hospital in three weeks, in good condition.

Vaginal Hysterectomy for Fibroids—Dr. J. RIDDLE GOFFE read this paper. He expressed the opinion that a fibroid tumor was always a menace to the health and life of its possessor, and that the sooner it was removed the better. The removal of a small fibroid was a simple matter. His plan was to attack the tumor through the vagina, doing a myomectomy, and leaving the uterus intact. He saw no objection to attacking a fibroma, no matter what its situation. By making a transverse incision in front of the cervix, and then a longitudinal incision the whole length of the vagina, and dissecting off the bladder from the vaginal wall, it was possible to retract the vaginal walls on each side to such an extent as to make them fit the interior of the bony pelvis. This gave as much room as was ordinarily obtained by the abdominal route. To deny a woman the happiness of married life and motherhood simply because she had a small fibroid in the uterus, seemed to him absurd. It should be removed through a vaginal incision. When the tumor reached up to the umbilicus, a laparotomy should be done.

Abdominal Hysterectomy for Fibroids—Dr. CHARLES N. DIXON JONES was the author of this paper, which was chiefly an historical sketch of the evolution of the operation of abdominal hysterectomy. He asserted that an important epoch in this evolution was the first performance of pan-hysterectomy, in America, by Dr. Mary A. Dixon Jones. Much credit was given to Dr. Stimson for his important pioneer work in connection with the use of the ligature.

Dr. PAUL F. MUNDÉ said that he agreed with Dr. Coe almost entirely. He had fought for years for the principle that a uterine fibroid, because it was a fibroid, did not call for any surgical interference; in other words, that it was not in itself of any more importance than a wart on the nose. So long as a fibroid did not grow, or produce pain or pressure symptoms, or hemorrhage, and so long as it was not likely by its peculiar position to nterfere with the health of the patient, such a fibroid, in his opinion, should not be disturbed. On the other hand, he believed that fibroids were "good tumors to watch," and he was accustomed to tell such patients, not that they had a fibroid, but that they must return in six months for further observation. He had great faith in the curette for the control of hemorrhage from fibroids, and he would, if necessary, repeat the curetting every two or three months. He had known patients to go ten or fifteen years under such treatment, until they had finally reached the menopause, and they had remained in good health thereafter. He always swabbed the uterus out with iodine or carbolic acid after the curetting. He had formerly used Apostoli's method, but had abandoned it, though he had no doubt that when used by experts it was useful It causes a reduction in the size of the tumors, and relieves the hemorrhages and other symptoms. He had never seen a fibroid disappear under such electrical treatment. He had known hæmorrhages to be quite well controlled by the faradic current, even when applied by a nurse. The use of ergot and hydrastis, thirty drops of each, several times a day, he had found useful, and less apt to disturb the stomach than the fluid extract of ergot given alone. If such palliative treatment were not successful, then he was certainly not averse to operation. He had always felt that if a fibroid developed low down in the pelvic cavity, and the woman was pregnant, he was justified in advising an abortion. If the patient preferred to take the chances of having a living child, and was willing to assume the risks to her own life incident to a cæsarean section, then that was the plan of treatment to pursue. Fibroids did not necessarily interfere with conception or with pregnancy. While he never hesitated to remove through the vagina anything easily reached by that route, he could not agree with Dr. Goffe as to the great advantages of vaginal hysterectomy for fibroids. This was largely a matter of individual experience and expertness. He did not believe in removing every little subperitoneal fibroid from a woman so that she could get married. It did not follow that such a tumor would cause any trouble during married life and he would not advise against such a woman marrying If the tumor gave any trouble, it would be time enough to interfere after marriage, and then it could be more easily taken away through the vagina He was in favor of supravaginal amputation, leaving the cervix in place and covered with peritoneum, so as to secure a better pelvic floor. However, where drainage was necessary, he would remove the cervix, and drain with gauze through the vagina.

Dr. E. J. ILL, of Newark, said that, out of about forty cases of fibroids complicating pregnancy, he had had a chance to do cæsearan section only once. He had kept these cases under close observation, and if the fibroid did not retract, which it usually did, however, then it was time enough to interfere. He had never seen anything but mischief from the use of the curette in cases of uterine fibroids; he had seen the capsule of a tumor opened by the curette resulting in sloughing and sepsis. For the control of hemorrhage, he had had the best results from the use of gossypium for a week or ten days previous to the period. In an experience with upward of three hundred tumors, he had never met with a fibroid which had undergone cancerous degeneration, although he had had many examinations made with the special object in view of determining this point. This being the case, there was no ground for urging operation upon a woman for fear that a small fibroid, giving rise to no symptoms, might ultimately become cancerous. He did not like to operate on fibroids through the vagina, except when the tumor was no larger than a fœtal head. When it became necessary to remove fibroids, it was usually desirable to remove the uterus also. The method he preferred was that described by Dr. Howard Kelly.

Dr. H. J. BOLDT did not think electricity was often indicated in these cases, but if it should be indicatd, it should be given by the gynecologist himself. He had had considerable experience in vaginal work, but to enucleate a tumor measuring four inches in diameter, per vaginam, unless it were a submucous tumor, was very difficult. It had been stated that subserous fibroids did not cause trouble, yet he had recently presented a subserous fibroid which had seriously complicated pregnancy.

Therapeutic Hints.

Hints on Typhoid Fever.—In hemorrhage use ergotin and digitalin. For insomnia and nocturnal delirium give morphine or codeine. For "fighting delirium" of the first stage give veratrine and tartar emetic. For "low muttering delirium" and weak heart give atropine. Kill the micro-organisms and render the stomach and intestines aseptic by giving zinc sulphocarbolate until the stools lose their odor—up to 100 grains daily. Calomel is useful in the first stage. If sweating is profuse use hydrastin. For subsultus tendinum give strychnine. In later stages, with blood in the stools, give silver oxide. For pneumonic symptoms use sanguinarin. Leptandrin is useful in constipation. Bismuth subnitrate is useful in gastric irritation.

M. G. PRICE, *Wisconsin Medical Record.*

Mercurial Salivation.—

℞ Acidi Tannici ..... ʒi.
Mel. Rosæ. ..... ʒii.
Aquæ ..... ʒvi.
M. S. As a gargle.

BARTHOLOW.

Chronic Bronchitis.—

Spts. Ætheris Nitrosi ..... ʒi.
Syr. Limonis q. s. ad ..... ʒiii.
M. S. Half to one teaspoonful every one or two hours.

SHOEMAKER.

Calomel.—I regard calomel as by far the most useful drug I have ever used. If calomel does not act when it should, give an injection of glycerin or soap and water. When first called to any fever, give from three to ten grains of calomel and follow with a saline. Ten grains of calomel every morning for three days in typhoid fever is a good beginning, particularly if it is desirable to make the bill light. Always make it a rule when you prescribe calomel either to give it in large doses once a day or in small doses for a few hours only. Do not prescribe, say, one grain of calomel every hour until the bowels move, for twenty grains may be given in this way and salivation result. Small doses of calomel frequently repeated, say one-tenth grain every half hour until ten doses are given, usually succeed in promoting activity of the bowels. When called to an infant with 105° to 106° temperature, in your prognosis give a ray of hope, and in your treatment, saying the child is two years old, give three or four grains of calomel. It has been my practice never to give acids while giving calomel, but always to give carbonate of potassium or of sodium.—C. E. BOYNTON, *Wisconsin Medical Recorder.*

Adenoids.—1. The removal of the lymphoid hypertrophies in the naso- and oropharynx, with the cure of the associated nasopharyngeal catarrh, will restore the potency and permeability of the nose. If done early, many local pathological changes may be avoided. 2. The general health may be more or less improved 3. The mental faculties and general intelligence will be improved. 4 Defects in speech and in hearing due to nasal troubles will disappear. 5. Deafmutism may be relieved. 6. The functions of taste and smell will be restored. 7. Reflex neuroses of various kinds will be modified or cured. 8. Nasal and supposed pulmonary hemorrhages will disappear. 9. Thoracic deformities will be relieved or cured. 10. The tendency to acute rhinitis, pharyngitis, laryngitis, bronchitis, and pneumonia becomes less and less with the restoration of normal respiration. 11. The dangers attending the presence of enlarged cervical lymph nodes will be avoided. 12. The invasion of various infectious diseases is less likely when the nasal mucous membrane is in a healthy state. 13. The danger of meningeal infection from the nasopharynx will be lessened.—*Archives of Pediatrics*

Strychnine.—Calomel is the only drug that is more useful than strychnine. Strychnine will enable you to make use, and good use, of veratrine and aconitine in fevers. Strychnine, digitalin, and glonoin are the triple alliance to face death when vitality runs low. When the pulse lacks sufficient power then is the time to give 1-20 to 1-30 grain strychnine hypodermically. It is not well to give full doses of strychnine as a routine treatment in fevers, but it should be used as indication demands. To meet collapse we may give 1-20 grain of strychnine every one or three hours until 1-3 of a grain has been given within the twenty-four hours.—C. E. BOYNTON, *Wisconsin Medical Recorder.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 20, 1901:

	Cases.	Deaths.
Measles	164	8
Diphtheria	130	18
Laryngeal Diphtheria (Croup)		
Scarlet fever	158	21
Smallpox	35	12
Chickenpox	14	
Tuberculosis	258	123
Typhoid fever	30	10
Cerebro-spinal meningitis		2

Treatment of Insanity by Rest in Bed.—Wizel is strongly in favor of this method. He has tried it thoroughly in a large number of cases during the past six months with very favorable results. He uses two wards for noisy and quiet cases, and separate isolation rooms. There is no restraint, but the patients are kept continuously under observation. It is difficult at first to classify the cases. In many cases a noisy patient put among quiet ones became quiet in a short time. In other cases his influence excites the other cases. If he cannot be kept in a ward, he is put in a separate room, but still the bed treatment is persisted in. The patient is given a separate attendant. Wizel holds that even for noisy patients this is much more satisfactory than isolation in a cell without observation. He does not find any difficulty in keeping his patients in bed. The avoidance of external sources of irritation is itself conducive to quietness, as is well recognized in the Weir-Mitchell treatment for neurasthenia; quarreling and fighting are diminished, and the patients are less likely to do themselves and others harm. They are much more easily watched, and hence bad habits can be more effectually prevented. By keeping the hands outside the bedclothes, it is possible to diminish masturbation. Since he has introduced this plan, the whole aspect of the asylum has changed. It is much more peaceable and more like an ordinary hospital. Its sedative influ-

ence is shown by the difference in the bill for sedatives. Since Russian writers have objected to this treatment, on the ground that it leads to constipation, loss of weight, facilitates masturbation and makes it difficult to get the patients to resume ordinary life. Many of Wizel's patients gained in weight, while in the other cases the loss was probably part of the disease. Constipation was not increased, while patients rise for their meals and go to the closet.—*Edinburgh Medical Journal.*

Ante-Mortem Invasion by Non-Pathogenic Microbes.—The human body while alive, is the natural home of the pathogenic microbe. When dead, it is taken possession of by others of many kinds, by the action of which it is rapidly decomposed. It is interesting, however, to note that even before death takes place micro-organisms of decomposition may obtain a footing in the body, and that in some cases the final cessation of life is hastened by the intrusion of non-pathogenic organisms which have taken advantage of the diminishing vital resistance of the tissues to implant themselves in their midst. At a meeting recently held of the London Pathological Society, which took place in the physiological laboratory of Guy's Hospital, Dr. J. H. Bryant reported the results of a bacteriological examination in three cases of ante-mortem thrombi. In the first case, which was one of mitral stenosis and tricuspid regurgitation, extensive ante-mortem thrombosis was found, in which streptococci and the staphylococcus albus were discovered. In the second case a pure culture of the proteus vulgaris was obtained, but the examination was not made until twenty hours after death. In the third case a pure culture of the bacillus subtilis was obtained from the thrombus in the left saphenous vein, and of the staphylococcus albus from the vein on the right side. This post-mortem examination was made four hours after death. It seemed possible, in the last case, that the bacillus subtilis had found its way into the blood through an old ulcer the patient had on his leg.—*The Hospital.*

Absinthe Poison and Other Toxic Essences.—At the meeting of the Academy of Medicine, held in Paris on June 11th, M. Laborde called attention to the baleful effects of absinthe and similar toxic essences. He asked that a committee previously appointed should be instructed as follows: That without delay, in conformity with the motion put forward by Parliament, the committee, in pursuance of its powers, should designate those liqueurs apéritips and drinks which contained such essences as were most harmful to the public health, with a view to putting a stop to their manufacture, distribution and sale. 2. That the study of the subject should be referred to the committee on alcoholism. 3. That any resolution which the Academy should pass after having heard the report of the committee should be sent to the public authorities and to the Deputies.

French Birth Rate Still Decreasing.—The returns of the French census, just made public, show that the population has increased only 330,000 in the last five years. Since 1872, when Alsace and Lorraine were taken from France, the population has grown from 36 1-10 millions to 38 6-10. In the same period Germany has added to her population 15 4-10 millions, the United States has swelled from 40 to 75 millions; Great Britain from 32 to 41; Austria from 20½ to slightly over 26; Hungary from 15 7-10 to 19; and Italy from 26 8-10 to 32. The increase of the above nations since 1872 averages about 12 millions each, while the increase of France during the same time has been in the neighborhood of two millions. Norway, it has been computed, doubles her population in 81 years, Austria in 62; England in 63; Denmark in 73; Germany in 98, and France in 334. The birth rate of France, which was 38 per 1,000 between 1770-1780, and 32 during the first ten years of the past century, is now only 22. The birth rate is decreasing, while marriages are fewer and less productive.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, United States Marine Hospital Service, during the week ended July 13, 1901:

HÆMOLYSIS.*

BY S. J. MELTZER, M.D.,

NEW YORK.

FROM THE DEPARTMENT OF PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

Introductory.—In the Transactions of this Association of 1898[1] a remark of mine is published in which I refer briefly to some experiments which I had made to determine the modifying influence of the peritoneal cavity upon the deleterious effect of alien blood. According to Hamburger,[2] salt solutions or serous fluids of an osmotic pressure differing from that of the blood of the animal, be they hypertonic or hypotonic, when introduced into the peritoneal cavity of an animal assume, after a while, the osmotic pressure peculiar to the blood serum of their host. This fact suggested to me the possibility that alien blood, too, might acquire a degree of adaptability to the new species by a preliminary stay in the peritoneal cavity of that species. To test this hypothesis, I introduced fresh defibrinated bullock's blood into the peritoneal cavity of a rabbit, left it there for three hours, removed it and strained it. Blood thus prepared, when introduced through the jugular vein into the circulation of a normal rabbit, proved to be less harmful than unprepared bullock's blood. Recently I have taken up this problem again, but studied it in the test-tube by the precise quantitative methods now in vogue in the recent marvelous studies of immunity and hæmolysis. The primary object of this paper is the communication of the results of my recent studies. However, since the entire subject of hæmolysis, as it has been developed in the biological investigations of the last two or three years, is of such immense importance, it was suggested to me to present also a review of the recent hæmolytic studies. This suggestion is the more justified as there is in the medical literature of this country, at least so far as I know, neither an original contribution to, nor a collective presentation of, this fascinating subject.† Acting on this suggestion, I shall therefore attempt to present a general review of the recent studies in hæmolysis before giving the results of my own studies.

Normal Hæmolysis.—Hæmolysis means in general the solution of blood. The term, however, is now chiefly employed to designate the separation of the hæmoglobin from the stromata of the red blood corpuscles. This end can be attained by a great number of different agents. In the present article, however, we shall, in conformity with other writers on this subject, deal only with biologic agents, the foremost of which is alien blood, or alien serum.

The early attempts at transfusion of animal blood into man showed that the normal blood of one animal is often detrimental to another animal. The fact was recognized quite early,[3] that the serum of one animal can dissolve the erythrocytes of another animal. Even the agglutinating effect of alien serum was recognized long ago,[4] although it must be admitted that its importance was not understood until the recent advent of the knowledge of bacterial agglutination, when the fact of hæmo-agglutination was rediscovered some six years ago by Bordet.[5] How dangerous, however, alien serum may be, was only recently demonstrated by the discovery by A. Mosso[7] of the extreme poisonous effect of eel's serum. One kilogramme of a mammal is killed by an intravenous introduction of 0.1 c.c. of eel's serum within three to four minutes. This serum is extremely hæmolytic, a trace of it rapidly dissolves mammalian erythrocytes in the test-tube.

Recent investigations have brought to light hæmolytic properties in a number of other biologic products. Cobra venom and some other snake poisons possess hæmolytic properties. Ehrlich[8] discovered that the tetanus toxin contains a hæmolytic agent—the tetanolysin. Bulloch and Hunter[9] describe the hæmolytic effect of filtered pyocyaneus cultures. Neisser and Wechsberg[10] discovered staphylolysin. Kobert[11] discovered the agglutinating effects of the four vegetable poisons, abrin, ricin, crotin, and robinin. Crotin exerts also a hæmolytic influence upon the blood of certain animals.

The development of the method of studying the hæmolytic effects of alien serum quantitatively in the test-tube was undoubtedly one of the most important factors in the rapid progress which has been recently made in the studies of hæmolysis and allied subjects. However, the all-dominating point in this new field of extremely important and interesting investigations was the discovery of hæmolysis by immunization, about three years ago. This discovery is so closely interwoven with the recent development of our knowledge of bacterial immunity that we shall devote a few remarks to the latter subject.

Bacteriolysis.—In the first period of the new bacteriological era, injection meant invasion of bacteria, and immunization was accomplished in a general way by inoculation with bacteria. After the toxins were discovered, followed soon by the marvelous successes of active and passive antitoxic immunizations—to mention only the toxins and antitoxins of diphtheria and tetanus, or ricin and antiricin, abrin and antiabrin—the opinion became prevalent that all immunizations are probably of an antitoxic nature; and so the bacterium or the cell in general became less conspicuous. By the excellent studies of Richard Pfeiffer and his coworkers, at about the middle of the last decade, it was, however, established that there is a distinct and specific antimicrobic immunization which does not protect against the evil effects of the toxins. The sera of animals immunized against cholera and typhoid, do not protect against the toxins of the bacteria in question, but are distinctly bactericidal. Pfeiffer found further that this bactericidal process has a morphological aspect, and is accessible to

*Read at the Annual Meeting of the Association of American Physicians, May 1, 1901, in Washington, D. C.

†Since reading this paper I find that the literature on this subject has been connectedly abstracted by Ludwig Hektoen in his excellent report on Pathology in "Progressive Medicine," Vol. I., 1901.

ocular observation. When, for instance, cholera vibrios were brought into the peritoneal cavity of a guinea-pig which contained serum of an animal immunized against cholera, the vibrios broke down into granula, and soon dissolved entirely. The process, which is termed bacteriolysis, is extracellular (is, therefore, not phagocytic), and is distinctly specific; that is, the immune serum of cholera dissolves only cholera vibrios and no other bacteria. Gruber soon discovered another specific morphological effect of the immune sera. Previous to their dissolution, the bacteria often gather into clumps or masses. This is the phenomenon of "agglutination" which has become so widely known in its practical application in the diagnosis of typhoid. The phenomena of bacteriolysis and bacterial agglutination are independent of one another, and are, it must be said again, distinctly specific. Thus it has been established that there are two distinctly different immunization processes; Immunization against bacteria and immunization against their toxins; or, as some toxins, like ricin, abrin, crotin, etc., are not the products of bacteria, we may express the broader conception by the terms immunization against foreign cells and immunization against their toxic products.

This conception of immunization against foreign cells apparently prepared the minds of the investigators for the studies which followed. While the lively discussion over bacterial agglutination was going on, Bordet, as mentioned above, rediscovered the agglutination of the red cells by alien serum. This, in conjunction with the already well-known lytic effect of serum of one animal upon the red blood corpuscles of another animal, brought out the parallelism between hæmolysis and hæmoagglutination on the one hand, and bacteriolysis and bacterial agglutination on the other hand. The effects of alien serum are also specific, as not every serum affects the red cells of all the animals, but serum of a certain species is hæmolytic or agglutinative for the erythrocytes of a certain other species of animals. Another point which is common to both processes is the fact that heating to 55° C. for half an hour deprives immune serum of its bacteriolytic property, and deprives also the alien serum of its hæmolytic action. When now, in view of the many points which the relations of immune serum to bacteria have in common with the relations of alien serum to erythrocytes, and when, further, the experiments of Belfanti and Carbone brought out the fact that the serum of animals in whom rabbit's blood has been injected is fatal to rabbits, the way was prepared for the last conclusion from these parallelisms, viz., that it ought to be possible to immunize against the red cells, just as it is possible to immunize against the bacterial cells. This explains how it came about that three investigators, independently of one another, have purposely planned the discovery of hæmolysis by immunization. The investigators were Bordet in Paris,[12] von Dungern in Freiburg,[13] and Carl Landsteiner in Vienna.[14] Bordet, whose publication of this discovery appeared a little ahead of those of the other investigators, has since followed up this subject with great ingenuity.

Hæmolysis by Immunization. Now, what is "hæmolysis by immunization"? Let us illustrate it by one of the experiments of Bordet. The normal serum of the guinea-pig has very little or no effect upon the red blood corpuscles of the rabbit, even when brought together and kept in the thermostat at 37° C. for many hours. If, however, a guinea-pig is treated several times at different intervals by subcutaneous or intraperitoneal injections of rabbit's blood, the serum of this guinea-pig acquires the capacity of dissolving the red cells of the rabbit with great rapidity, just as the serum of an animal which has been treated by bacterial injection dissolves such bacteria. This acquired hæmolysis is specific. The serum of a guinea-pig immunized by rabbit's blood dissolves rapidly only the cells of rabbits, while it retains its normal indifferent behavior toward the red cells of other animals. The serum of immunized animals acquires also a specific agglutinative power towards the red cells of the animals in whose blood the immunization was accomplished. The addition of the serum to such blood causes a rapid falling out of the red corpuscles which clump together at the bottom of a test-tube to a dense mass.

Hæmolysis by immunization and hæmo-agglutination have now been studied with uniform results in a great many species of animals, of which chickens and pigeons (von Dungern[15]), geese (Metchnikoff[16]), and frogs (Krompecher[17]) deserve special mention. With the nucleated red cells of the blood of these animals a quantitative study of the hæmolytic effect is possible not only in the test-tube, but also in the hanging-drop under the microscope. The number of free nuclei indicates the degree of hæmolysis. Furthermore, with these characteristic corpuscles also the specific character of hæmolysis and agglutination is conveniently demonstrable in the hanging drop. When, for instance, chicken blood and the blood of a mammal, say a guinea-pig, are thoroughly mixed, and to a drop of this under the microscope a droplet of the serum of a rabbit, immunized by chicken blood, is added, it can then be observed that during the period of agglutination the nucleated red cells of the chicken gather into small heaps, while the red cells of the guinea-pig remain evenly distributed throughout the entire field. In a later stage, when the hæmolysis takes effect, the red cells of the guinea-pig remain unchanged, while nothing but nuclei can be seen of the chicken cells.

Immunization is accomplished by the usual methods, *i. e.*, by subcutaneous, intraperitoneal, or intravenous injections. In a very recent communication, however, Metalnikoff[18] reports that he attained immunization also by feeding one animal with the blood of another animal. In a previous communication by Uhlenhuth[19] on anti-proteid immunization, of which we shall speak presently, the possibility of an intra-stomachal immunization is mentioned.

Other "Immunization" Reactions.—Before continuing further our report on hæmolysis, we shall stop to call your attention briefly to a number of other remarkable results which the very recent studies in hæmolysis and immunity have brought to light. In the first place the conception of immunization against foreign cells, which was derived, as stated above, from the possibility of immunization against red cells as well as against bacteria, was soon extended with success to other body cells. V. Dungern[20] has immunized animals against ciliated epithelia. When these epithelia are introduced into the peritoneal cavity of a normal animal, the cilia continue their movements for quite a long time. If, however, the animal has been treated beforehand with injections of an emulsion of such epithelia, the cilia stop their movements very soon after introduction in the abdominal cavity, and the entire cell becomes rapidly degenerated. The same differences can be observed in the sera of the animals within test-tubes.

In connection with these results, the idea found expression that it might be possible to obtain a serum protective against malignant epithelial growths. Metchnikoff[21] has immunized animals against leucocytes. These cells become rapidly dissolved in the

peritoneal cavity or the serum of animals which have been previously treated by injections of the emulsion of the spleen or lymph glands. Metchnikoff,[22] Landsteiner[23] and Moxter[24] have immunized sheep against spermatozoa. These cells lose their motility very rapidly in the peritoneal cavity of animals that have previously received injections of the same kind of cells. All these immunizations are distinctly specific. If, for instance, the animal has received injections of sheep's spermatozoa, its peritoneal cavity will exert no influence upon the spermatozoa of the horse, etc. Spermatozoa of immunized animals show also the phenomenon of specific agglutination.

Furthermore, the hæmolytic studies brought out facts which stimulated researches regarding immunization against animal substances of a non-cellular character, and these have had extremely interesting results. Tchistovitz,[25] Bordet,[26] and Nolf[27] found that the specific immune sera which affect the red cells by agglutination and dissolution cause also a distinct precipitate in the blood serum of the species by whose blood or serum the immunization was accomplished.

Bordet[28] found, further, that after the injection of milk into an animal the serum of this animal, when added to milk, causes a precipitation of the proteids of the milk. And Wassermann[28] has shown that this reaction is a specific one. For instance, when the injections are made with cow's milk the serum will cause precipitate in cow's milk only, and not in the milk of any other animal.

Walter Myers[30] and Uhlenhuth[31] found after the injection into animals of certain proteids the sera of these animals produce a precipitate in the proteids employed in the injections; and this reaction, too, is distinctly specific. For instance, when a rabbit is immunized by the whites of hens' eggs the serum of this animal gives no precipitate with any other kind of a proteid except with the egg-albumen of a hen's egg.

Practical Application.—The specific precipitation of the immunized blood serum found recently a very interesting practical application. Uhlenhuth[32] and Wassermann and Schuetze[33] have evolved from it a very delicate method for distinguishing with absolute certainty human blood from that of other animals—*except that of monkeys!* After the injection of human blood into rabbits the serum of the latter causes a characteristic turbidity and flocculent deposit in the human blood, even if this is in the form of an old small dry spot. The reaction is present even when the human blood is diluted 1:50,000 (Stern[34]). The forensic importance of this method is apparent. Further studies have shown that the immunization in question can be accomplished not only by human blood, but also by peritoneal exudates;[35] and what even is more striking, by albuminous human urine.[36] Serum made to be immune by any of these methods gives a precipitate not only in the human blood, but also in dilute albuminous human urine. The outlook for further progress in this direction is very bright.

Mechanism of Hæmolysis by Immunization.—Turning again to hæmolysis by immunization, I have to record the great progress made in the understanding of the mechanism of this process, and here again we have to recur to bacteriolysis. In the bacteriology of only a few years ago we often met the term "Pfeiffer's phenomenon." It meant the observation of Pfeiffer that immune sera dissolved bacteria only within the peritoneal cavity, not outside of the animal's body. Metchnikoff,[37] however, has shown that the bacteriolytic process can be observed also in the test-tube, if peritoneal exudate is added to the immune serum; and Bordet[38] has shown further that even the immune serum alone will dissolve bacteria outside of the body, if it be very fresh. The immune serum loses something by standing, but this can be regenerated by the addition of serum from a normal animal. Immune serum which has been made inactive by heating at 55° C. for half an hour can also be made active again by the addition of such normal serum. Reviewing all these facts, Pfeiffer[39] has formulated a theory which has met with nearly universal approval. Fresh immune serum according to this theory, consists of two parts; one component is not easily destroyed by heat—it is thermo-stable; the other one is destroyed by such a low temperature as 55° C.—it is thermo-labile. The latter substance is a ferment-like body, and is present in the normal serum of animals. The thermo-stable part—which is the new, immunized part of the immune serum, and therefore is the real immune body—is in itself harmless to the bacteria; but it forms the means of bringing the normal proteolytic ferment, present in the normal serum, to act upon the bacteria, to dissolve them. The fresh immune serum contains both; the ferment-like body, however, is very sensitive to all abnormal influences, perishes soon, and is readily destroyed by a temperature of 55° C. When this occurs, the immune serum is then inactive, and contains only the inactive immune body; but by the addition of fresh normal serum new ferment bodies are added, and the immune serum becomes regenerated or "reactivated," to use the technical term.

When Bordet had discovered the hæmolysis by immunization, he subjected it to the same tests employed in bacteriolysis, and found that heating the serum to 55° C. deprived it of its hæmolytic power, and that the addition of normal serum restored this again; thus the inactive serum is regenerated. Bordet, therefore, assumes that the hæmolytic immune sera, like the bacteriolytic sera, also consist of two parts—a new, thermo-stable, harmless immune body, and a thermo-labile, sensitive, enzyme-like body, which latter is present also in the serum of normal animals.

We may mention briefly that the hæmo-agglutinating and the precipitating properties of the immune serum show a resisting power, equal to that of the immune body. A temperature of 60° C. for one hour does not affect them.

Ehrlich and Morgenroth's Studies of Hæmolysis.—In a long series of ingenious experiments the mechanism of hæmolysis has been subjected to a profound analysis by Ehrlich and Morgenroth,[41] who brought to light a number of important facts and general principles, and whose views are now accepted by a majority of the investigators in this new field. The terminology of those writers is new and somewhat complicated, and has its origin in Ehrlich's so-called "lateral-chain theory of immunity." As Ehrlich's theory has been very fruitful in the discovery of many new facts, and is now accepted as the best working hypothesis by a great number of leading bacteriologists, it will not be out of place to give here a brief sketch of it.

Ehrlich's Lateral-Chain Theory.—Ehrlich's color-analytical studies led him to the conception[42] that the living protoplasm has, besides its essential part, a great number of lateral mechanisms. The essential part (*Leistungskern*) is that which distinguishes one cell from another—for instance, a nerve cell from a blood cell—while the object of the lateral mechanism, which Ehrlich termed lateral or side chains (*Seitenketten*), is to catch external substances and chain them to the main body of the cell. Thus the process of assimilation, Ehrlich thinks, is carried on by means of these mechanisms; the highly complex large food molecules are trapped by these catchers, split by means of some ferment, and made ready for the use of the cell body. These

mechanisms Ehrlich designates now as *receptors*. According to him, each receptor is adjusted for only one kind of substance, is specific, receptor and substance being fitted for one another like key and lock. By means of these receptors not only food, but many other things can be grasped and firmly fastened to the cells; for instance, ferments and toxins, provided these cells have the receptors specifically adapted to these toxins or ferments. Animals whose nerve cells, for instance, have no receptors for the tetanus toxin are immune to tetanus. At present Ehrlich distinguishes three orders of receptors:

First Order, single, uncomplicated receptors; these receive, among others, toxins and ferments.

Second Order, single receptors, complicated by ferments; these receptors serve, as mentioned above, the process of assimilation.

Third Order, double receptors; these Ehrlich now terms *amboceptors*. We shall encounter these terms later in discussing hæmolysis.

When the receptors have trapped and fastened corresponding substances, they, too, become fixed, and therefore are lost to the cell body; the loss, however, is soon made up by the cell regenerating new receptors. Now, Ehrlich assumes that when by frequent introduction of substances the loss and regeneration of the receptors become a repeated occurrence, the cell body, if not succumbing to the overtaxation, is stimulated to overproduction of the receptors—compensatory hypertrophy (Weigert)—which then, Ehrlich further assumes, are thrown off into the surrounding fluid, and are finally brought into the blood-stream. Hence immunization—*i. e.*, frequent introduction of a specific substance—leads finally to an overflooding of the blood-stream with corresponding specific free receptors. If now the specific substance, say tetanus toxin, is introduced into the blood, it is caught and fixed by the free-swimming receptors within the blood, and thus is prevented from getting within the reach of the nerve cells and their receptors—hence the success of active immunization. Furthermore, if such blood containing free-swimming specific tetanus receptors is injected into another animal, it will protect this animal also against the effects of the toxin, because the free receptors within the blood of the new host will catch and fix the invading toxins, and thus prevent them from doing further damage. Antitoxin, according to Ehrlich's theory, is the specific receptor torn away from the cell body and swimming within the blood, ready to catch its special associate, the specific toxin.

Moreover, according to Ehrlich, not only the cells, but also all other units of living protoplasm consist of two parts, an essential part and a part whose task it is to form specific unions with other substances or cells. For instance, ferments and toxins consist of a *toxiphoric* or *toxizymotic* group through which each toxin or ferment differs from every other, and exerts its specific activity, and a *haptophoric* group through which the ferments or toxins become fixed to the receptors still attached to the cells or detached from them.

From the foregoing statement it may be seen that according to the kind of immunization, the blood contains detached receptors of the first or second order, *i. e.*, single receptors, uniceptors or receptors of the third order, amboceptors, *i. e.*, bodies which, like double clamps, contain two receptors. With this latter kind of receptors, according to the views of Ehrlich and Morgenroth, we have to deal in hæmolysis, to which we now return.

The thermo-sensitive component of the hæmolytic body (hæmotoxin) was at first termed by Ehrlich and Morgenroth "Addiment;" they call it now "Complement." The thermo-stable part they previously termed "Immune body" in hæmolysis by immunization, and "Intermediary body" in normal hæmolysis; now they term it, as stated above, "Amboceptor" in both cases. The latter term has not yet been employed by any other writer. The terms "immune body" and "complement" have the advantage over other designations, inasmuch as they express the facts irrespective of any theoretical interpretation.

For the proper study of the exact relations of the complement and immune body to one another and to the red-blood corpuscles, it was indispensable to obtain each component separately. This is an easy task as far as the immune body is concerned. The heating of the serum to 55° C. destroys the complement in most cases, thus leaving the immune body in the inactive serum in practically a pure state. It was quite a difficult task, however, to obtain the specific complement free from the immune body and other complements always present in any serum. The study of the ingenious methods invented by Ehrlich and Morgenroth to throw light into the intricate problems, is quite interesting and instructive. I shall, however, restrict myself here to the relation of only one of the fundamental experiments.

A certain number of the red-blood corpuscles which were used for immunization were added to the immune serum and immediately put on ice, where the mixture remained for some time; then by means of the centrifuge the blood cells were separated from the serum and mixed with a proper quantity of physiological salt solution. In this state no solution of the red cells took place. Neither had the addition of inactive (heated) serum (immune body) any effect; but the addition of normal serum (complement) led immediately to hæmolysis. Then again the addition of fresh red-blood cells to the decanted immune-serum cells caused no solution of the blood corpuscles; such a solution, however, soon took place on the further addition of inactive serum. The different phases of this experiment show clearly that during the stay on ice the red-blood corpuscles took up from the immune serum all the immune bodies and none of the complement, which remained in a pure state in the centrifugated immune serum.

From this and many other experiments, the details of which cannot be given here, Ehrlich and Morgenroth conclude that immune body and complement exist in a separate state within the immune serum. The red blood corpuscles, when brought in contact with the immune serum, take up a certain amount of the immune body and form a firm union with it, but take up nothing of the complement. The latter, however, is taken up by another receptor of the immune body, and through this connecting link the zymotic complement exerts its dissolving influence on the red cells. Accordingly, the immune body is provided with two receptors, a sort of a double clamp; it grasps with one of the receptors the red cell and with the other binds the complement. The immune body, however, has a greater affinity, at least within the artificial immune serum, for the red-blood corpuscles than for the complement. The junction between immune body and red cell can be accomplished in a shorter time and at a lower temperature than that required for a successful union of immune body and complement. According to Ehrlich's theory the immune body is a receptor of the third order which by the act of immunization has been thrown off from the red

cells into the blood stream of the immunized animal.

In connection with the foregoing we should mention that, according to the experiments of Nolf,[43] it is the stroma and not the hæmoglobin of the red corpuscles which binds the immune body. Furthermore, according to v. Dungern[44] immunization produces only immune bodies, while the proportion of complements which are normally present in the serum remains unaltered.

By a further analysis Ehrlich and Morgenroth have proved that normal hæmolysis is similar in nearly all respects to the hæmolysis caused by artificial immunization; the hæmolytic body—the normal hæmotoxin—consists also of the same two components, and the relations to one another, as well as to the red corpuscles, are the same as described above for the immunization hæmotoxin. Normal hæmolysis is nothing else than a result of immunization which has taken place at one time or another during the life of the animal. Furthermore, when the normal serum of one animal species dissolves the red blood corpuscles of two or three or more species of animals, this serum has been found to contain just as many separate specific hæmotoxins. In normal goat serum which possessed the power to agglutinate human blood as well as the blood of rabbits and pigeons, Malkoff[45] found that upon the addition of human blood to the serum, which was followed by a rapid agglutination of the red cells, the supernatant serum retained its agglutinating power for the blood corpuscles of the other two species in question. Again normal goat serum dissolves the red blood corpuscles of the rabbit as well as those of the guinea-pig. By adding guinea-pig's blood to inactive serum, and then centrifugating it, Ehrlich and Morgenroth proved that the sedimented blood cells contain the immune body for the guinea-pig's blood, while the supernatant serum contains the immune body for the rabbit's blood. By filtration of normal goat serum through a "pukalla filter" Ehrlich and Morgenroth established further, that the filtrate contains the entire complement of the hæmotoxin for the guinea-pig's blood, while nearly nothing of the complement for the rabbit's blood passes through the filter. All of which goes to show that the normal serum of the goat, which dissolves the blood cells of two species, contains separate immune bodies, as well as complements for each species.

Ehrlich and Morgenroth have also studied the effect of injections of blood of one individual into another individual of the same species. They found in fact that the serum of the receiving individual exerts a hæmolytic effect upon the blood of a limited group of individuals of the same species. The individuals of this group, however, may differ among themselves in their behavior towards the serum of another immunized individual. The hæmotoxins affecting the individuals of the same species Ehrlich and Morgenroth term "Isolysins" in contradistinction to the hæmotoxins affecting those of another species which they term "Heterolysins." Ehrlich and Morgenroth could not establish the existence of "Autolysins," *i. e.*, the serum of an animal which was treated by injections with its own blood, did not acquire a dissolving power over its own red blood corpuscles.

Finally it has been established by Ehrlich, Bordet, and many other investigators, that by injections of immune sera, or normal sera containing specific hæmolysins, specific *antihæmolysins* are produced in the serum of the receiving animal, the efficiency of which can be easily demonstrated in a qantitative way in the test-tube. According to Ehrlich the antibodies enter into a combination with the haptophoric group of the complement, thus preventing it from joining the immune body and affecting the red blood corpuscles. A. Schuetze[46] and Paul Mueller[47], however, report that in their experiments the antibodies were attached to the immune bodies.

There are some differences between the views of Ehrlich and Bordet which deserve to be pointed out briefly. The ferment-like component of the hæmotoxin (Ehrlich's complement) is termed by Bordet and Buchner[48] "Alexin," and both writers assume that it is one and the same proteolytic enzyme which causes all the specific cases of hæmolysis as well as bacteriolysis. We have seen above that Ehrlich assumes the existence of a specific complement (alexin) in each and every case of specific hæmolysis, and it seems to me that Ehrlich's view is conclusively borne out by his experiments.

Another point of difference is the way both authors conceive of the relation between the complement (alexin) and the red blood corpuscles. Ehrlich's view we have stated above; the complement becomes attached to the immune body which in turn is attached to the red cell, and hence the name "intermediary body" for the immune body. Bordet assumes that the alexin (complement) directly attacks the red blood corpuscle, but not until the latter has been prepared in a certain unknown way by the immune body, and hence Bordet's name for the latter, "Substance sensibilatrice."

Metchnikoff[49] terms the immune body "fixator" and the complement "citase," which latter connotes Metchnikoff's theory that the ferment has its origin in the white cells. (Paul Mueller[50] uses the term "copula" for the immune body.)

A few words should be said regarding the term "immunization" employed by all writers for the different specific reactions enumerated in this paper. With the term immunization we are wont to combine the conception of the preparation of an entire complex organism to resist the effects of an infection or intoxication. In the present line of studies the term "immunization" is employed to indicate that by the repeated invasion of foreign organic substances a new element, probably of cellular origin, is created in the blood, by means of which the intruder is unfavorably affected. It cannot be denied that in the abstract both definitions have a common ground, since by repeated attacks multicellular or unicellular organisms acquire offensive powers against their assailants. In *praxi*, however, the new application of the term "immunization" is bound to lead to some confusion. Here is an illustration, for example, taken from my own experience: In order to immunize a rabbit against the red cells of the guinea-pig, I injected blood of the latter animal into the ear-vein of a rabbit. The third injection completed the immunization, and the serum of the rabbit dissolved the red cells in a few minutes; this successful immunization, however, sometimes kills the rabbits. The stromata of the dissolved red cells of the guinea-pig form thrombi in the vascular system of the rabbit. Here is a successful immunization which kills the immunized animal. The immunization of a cell is one thing, and the immunization of an animal is quite another thing. It seems indeed desirable to have for the unicellular reactions a separate designation, leaving the term "immunization" for the acquisition of defensive powers by the complex organism. However, hæmolysis is already crowded with new terms, and I do not feel impelled to the invention of another.

My Own Experiments.—I come now to my own experiments. As stated in the introduction, my original undertaking was the study of the changes which alien blood might undergo by a temporary stay in the peritoneal cavity of the receiving species. In the present line of investigation the question was more precise, *viz.*, Do the hæmolytic and agglutinating prop-

erties of alien serum suffer any changes by such a stay? This question can be studied in the test-tube with the reasonable expectation of obtaining precise, quantitative results. But for that purpose I had to employ serum instead of blood, and this serum had to have hæmolytic and agglutinating properties which not all sera possess. In my previous experiments I tested the effect of bullock's blood upon rabbits. The preliminary work in my present experiment was therefore to establish the effects of bullock's serum upon the red blood corpuscles of the rabbit. As far as I can see, there are no statements regarding this point in the recent literature on hæmolysis. It will be, therefore, not out of place to give here a brief account of the results of my preliminary experiments.

Agglutinating Power of Normal Bullock's Serum.—Regarding agglutination the statement can be very brief: In the numerous tests I have made I have never observed that normal bullock's serum exerts any agglutinating influence upon the red blood corpuscles of the rabbit.

Hæmolytic Power of Normal Bullock's Serum.—It is different, however, with hæmolysis. Bullock's serum dissolves the rabbit's red cells. Before going into particulars I have to say a few words regarding my method. Fresh defibrinated rabbit's blood was employed and always diluted 1 to 10 of 0.85 per cent. salt solution. Two c.c. of this diluted blood was put into a narrow test-tube and a variable quantity of fresh bullock's serum was added. The test-tubes were then kept either in a thermostat at 37° C., or at the room temperature, and then the degree of the eventual solution and the time of its apperance were noted.

As stated above, the red blood cells of the rabbit are promptly dissolved by bullock's serum. The degree of the hæmolytic effect varies with each individual from which the serum has been obtained—a condition which bullock's serum shares with many other normal hæmolytic sera. The variation, however, in our case was confined to narrow limits, 0.5 c.c. of the weakest bullock's serum dissolved two c.c. of rabbit's blood (1:10) in one hour at room temperature, while there were bullock's sera, 0.2 c.c. of which dissolved the same quantity of rabbit's blood within ten minutes, also at room temperature. Higher temperatures, of course, hastened the solution in every case. By the term "solution" I mean that the blood became laky, perfectly translucent, with no sediment; the stromata, however, could be seen as a fine, flocculent suspension; shaking the test-tube could not alter the condition.

Heating the serum to 55° C. had hardly any influence. To deprive the serum of its hæmolytic power it was necessary to keep it at 57° C. or 58° C. for at least fifty minutes. The serum lost its hæmolytic power when kept at room temperature for ten to fourteen days. At a low temperature the hæmolytic power was preserved much longer.

The hæmolytic property of bullock's serum differs from that of many other hæmolytic sera with regard to regeneration; of this, however, we shall have to speak later.

Influence of a Stay of the Bullock's Serum in Peritoneal Cavity.—After this preliminary statement I can now turn to the problem in hand. The chief result can be briefly stated. *When normal fresh bullock's serum is brought into the peritoneal cavity of a rabbit, and left there for three hours, the recovered serum is found to have lost all or most of its hæmolytic power.* The loss is less when the stay is shorter. It is impossible to keep the serum in the abdominal cavity much longer than three hours, for the animal usually dies after three and a half hours.

In most of the experiments a part of the serum was absorbed during its stay in the peritoneal cavity. I saw, however, two animals from which I recovered, after three hours, more fluid than I had introduced. In neither of these cases was there any difference regarding the loss of the hæmolytic power. In two experiments in which I found the hæmolytic power only considerably reduced, I introduced the recovered serum into the peritoneal cavity of another rabbit, and removed it again after fifteen minutes. The serum was now found to possess no hæmolytic power whatsoever. On the strength of these observations we can base the following statement: The normal hæmolytic power of bullock's serum for the red blood corpuscles of the rabbit disappears during a stay in the peritoneal cavity of this animal; the disappearance is the greater the longer the stay, and is independent of the absorption of the fluid; disappearance takes place even during the first fifteen minutes.

I will transcribe a few notes of experiments for illustration:

1a. 2 c.c. rabbit's blood + 0.5 c.c. nor. bullock's serum=after 50 minutes, clear solution.	19° C.
1b. 2 c.c. rabbit's blood + 0.5 c.c. per. bullock's serum=slightly dissolved above dark sediment after 17 hours.	
2a. 2 c.c. rabbit's blood + 0.5 c.c. nor. bullock's serum=in a few minutes perfectly laky.	Inthermostat at 37°C.
2b. 2 c.c. rabbit's blood + 0.5 c.c. per. bullock's serum=after 24 hours undissolved.	
3a. 2 c.c. rabbit's blood + 0.5 c.c. nor. bullock's serum=after 10 minutes dissolved.	
3b. 2 c.c. rabbit's blood + 0.5 c.c. per. bullock's serum=after 70 minutes very slight solution; after nine hours quite laky, black deposit.	21° C.
3c. 2 c.c. rabbit's blood + 0.5 c.c. per. per.* bullock's serum=after 9 hours no change whatsoever.	

Absence of Hæmolysis Not Due to Antihæmolysin.—What is the nature of this change in the hæmolytic power which takes place in the peritoneal cavity? The disappearance of the hæmolytic power may be due either to the subtraction of one of the components of hæmolysis, or to the addition of antihæmolysin. I shall discuss the last proposition first. I tested it by determining the minimum quantity of normal bullock's serum, which still dissolved fairly distinct in a reasonable time, and then adding to it peritoneal bullocks' serum. The outcome was negative. Even the addition of 1 c.c. of the peritoneal bullock's serum had no visible influence upon the hæmolytic effect of the predetermined minimum of the normal bullock's serum. I have also washed out the normal peritoneal cavity with physiological salt solution, and tested the fluid for antihæmolysin—with a negative result!

Disappearance of Hæmolytic Power in the Peritoneal Cavity of a Dead Animal.—Moreover, the following interesting fact speaks also against the assumption that the loss of hæmolytic power within the abdominal cavity is due to an addition of some factor. I have repeatedly established that the hæmolytic effect disappears also when the bullock's serum is kept for a few hours in the peritoneal cavity of a dead rabbit. The loss is somewhat smaller than that which takes place in the living animal. Now, it is not very probable that a secretion of an antihæmolysin takes place in the peritoneal cavity of a dead animal. That absorption of fluid from the peritoneal cavity of a dead animal takes place, we know from the experiments of Hamburger[51] and of Adler and myself.[52] With the definition of absorption, as given by Adler and myself, the process is easily understood. We divide absorption into two phases. The first

*Per. per. means that the peritoneal serum was transferred into the peritoneal cavity of another rabbit for 15 minutes.

phase is the entrance of fluid from the peritoneal cavity into the interstitial spaces; the second phase is the entrance of the fluid from the interstitial spaces into the blood stream. The latter phase does not occur in the dead animal, as there is no blood stream. The first phase is effected chiefly by imbibition, a process which takes place also in dead tissue. Therefore the entrance of the whole fluid, or part of it, from the peritoneal cavity into the surrounding interstitial tissue can and does take place also in dead animals.

The disappearance of hæmolytic power of the serum from the peritoneal cavity is apparently due to a subtraction, to an absorption of one of the components of hæmolysis. But which of the components is it, the immune body or the complement? Regarding the immune body, the determination was easy. Bullock's serum, heated at 57° C. for one hour, as a result of which it becomes inactive (immune body), was added to the inactive peritoneal serum, and both were added in sufficient quantities to rabbit's blood. It had no influence. It is, therefore, not the immune body which becomes absorbed in the peritoneal cavity.

It would thus appear that it could be only the complement which became absorbed. However, the test was disappointing. Following the lead of Bordet Ehrlich etc., I have tried to regenerate the inactive peritoneal serum by the addition of normal serum. I have tried fresh normal serum of the rabbit, guinea-pig and the sheep; I have tried horse serum,* which is said to be rich in various complements—but all failed! I followed out the suggestion of Delezenne[53] and obtained by centrifugation of rabbit's blood fresh serum ready for use half an hour after the blood was drawn—but all in vain! So far, I have not succeeded by the addition of any normal serum in regenerating the peritoneal serum.

Inactive Bullock's Serum Cannot Be Regenerated.—However, the failure to regenerate by normal serum does not necessarily indicate that it is not the loss of the complement which made the peritoneal serum inactive. According to universal experience, the inactivity of the heated serum is surely due to the destruction of the complement. Nevertheless, I did not succeed in regenerating the heated bullock's serum by any normal serum. Neither could I regenerate bullock's serum which had become inactive by standing fourteen days at room temperature. It is a singular and interesting fact that the hæmolytic force of normal bull's serum, when once made inactive cannot be regenerated, at least not by the usual methods. The only other similar exception I know of is that of eel's serum, of which Ehrlich and Morgenroth[54] report that, if it is once made inactive (by heating it fifteen minutes at 54° C.), it cannot be made effective again.

Effect of the Peritoneal Cavity upon "Immune Serum."—The next step in the line of my investigation was the inquiry whether "immune serum" also becomes inactive by a temporary stay in the peritoneal cavity. I have selected for my study the serum of rabbits, immunized by guinea-pigs' blood. To save material and time, I immunized the rabbits by injecting guinea-pigs' blood into the circulation through the ear veins. I shall record here a few observations made, which I have not seen reported elsewhere. I used for each injection only 1.5 c.c. of the blood, repeating them at intervals of five to six days. I could never make more than three injections—a fourth injection was sure to kill the animals; they usually died under convulsions within four to five minutes after the injection. They die sometimes even soon after the third injection, and therefore one must, when the third immunizing injection is made, be ready to obtain the blood, if one is not to lose the experiment. Intravenous injection of blood into an animal against which it is already immunized, kills the animal, probably through the formation of thrombi in vital points, either by the agglutinated foreign blood cells, or by the masses of the stromata from the dissolved red cells.

Before making the second or third injection, I often obtained some blood from the ear vein of the rabbit, and tested the effect of the serum upon the blood cells of the guinea-pig. I thus observed that agglutination of the red-blood corpuscles was the first effect which appeared in the serum of the immunized animal. It appeared sometimes even after the first injection, while there was as yet no sign of hæmolysis. After more injections, when the hæmolytic effect became intense and rapid, the process of agglutination could hardly be observed. In some cases, however, both phenomena were distinctly present. In these cases the agglutinating effect starts immediately on the addition of the serum to the blood, and soon dense red masses are seen to accumulate at the bottom of the test-tube, in which the hæmolytic process progresses quite slowly. Heating the serum for thirty minutes at 55° C. destroys hæmolysis, but not agglutination. By this means the process of agglutination can be made visible even in cases in which the process of agglutination can hardly be observed.

We come now, again to our leading experiment. Serum of an immunized rabbit was introduced into the peritoneal cavity of a normal rabbit, left there for three hours, and then recovered. Such peritoneal serum, when added to guinea-pigs' blood, *agglutinated it, but caused no hæmolysis whatsoever.* Addition of immunized rabbits' serum, made inactive by heating, to peritoneal serum, had no regenerating effect. But addition of fresh normal rabbits' serum to the immunized peritoneal serum regenerated it completely; the mixture of both sera dissolved guinea-pigs' blood as readily as the active immunized serum alone. The following notes of the experiments are sufficiently illustrative:

4a. 2 c.c. "g.-p. bl."* + 0.5 "C. im. ser."=dissolved in a few minutes.
4b. 2 c.c. "g.-p. bl."* + 0.5 "C. per. im. ser."=after 8 hours undissolved.
4c. 2 c.c. "g.-p. bl."* + 0.5 "C. im. ser. 55"=after 8 hours undissolved.
4d. 2 c.c. "g.-p. bl."* + 0.5 "C. per. im. ser." + 1.0 "fr. rab. ser."=dissolved in a few minutes.
4e. 2 c.c. "g.-p. bl."* + 0.5 "C. im. ser. 55" + 1.0 "fr. rab. ser."=dissolved in a few minutes.

There was prompt agglutination in every one of the five tests.

These experiments teach us that immunized serum also, when kept for a few hours in the peritoneal cavity, becomes inactive. But here we have seen that on the addition of fresh serum of a normal rabbit, it becomes active again, and this furnishes us with the looked-for proof that the loss of the hæmolytic power in the peritoneal cavity is due to the disappearance of the complement from the remaining fluid in the peritoneal cavity. Agglutination does not seem to become visibly affected by a stay in the peritoneal cavity.

Chief Conclusions.—Normal and immunized serum lose their hæmolytic power during a prolonged stay in the peritoneal cavity. The loss is due to the dis-

*"g.-p. bl."=guinea-pigs' blood, 1:10. "C. im. ser."=serum from immunized rabbit C. "C. per. im. ser."=Peritoneal serum from immunized rabbit C. "C. im. ser. 55"=serum from immunized rabbit C. heated at 55° C. "fr. rab. ser."=fresh serum from normal rabbit

*I wish to thank Dr William H. Park, who kindly provided me with horse serum

appearance of the toxic component, the complement of Ehrlich, or the alexin of Bordet and Buchner. The disappearance means absorption; and the disappearance of the complement in a much greater proportion than the balance of the fluid means elective absorption. However, as this elective absorption takes place also in a dead animal, it cannot be a vital phenomenon; it is rather probable that it has its explanation in some laws of osmosis and imbibition.

THE PRINCIPLES OF DIAGNOSIS OF LESIONS OF THE SPINAL CORD.*

By JOHN PUNTON, M.D.,

KANSAS CITY, MO.

As we stand upon the threshold of a new century it is both interesting and instructive to pause and review in detail the principal features that have marked the progress of medical science during the past decade. That the relative importance of thees may be variously estimated from different standpoints is possible, but it is very certain that modern medical advance owes more allegiance to the practical power and development of microscopical research than to all other agents combined. It is the microscope, therefore, and its various collateral appliances that we recognize to-day as furnishing us the most useful knowledge, as well as practical results, and that which underlies all scientific medical progress. More especially is this true when we come to study the complex architecture of the nervous system and the nature and character of the lesions causing its derangement. It is to certain principles thus obtained that I desire to call attention, and more particularly those that directly pertain to the diagnosis of lesions of the cord. Prior to the introduction of the microscope into practical medicine by Leuwenhoeck in 1690, nothing whatever was known concerning that which we regard to-day as the most essential knowledge concerning the finer structure of the nervous system. But with all the marvellous changes incident to perfecting the microscope, together with the various processes of staining, as well as methods of hardening the tissue (more especially those developed within the last decade), a complete revolution has taken place in our former conceptions of the structure and function of the cell and its histological appendages, resulting in the creation of the neuron theory. This is gradually but certainly becoming more firmly established by the correction of former erroneous inferences and the displacement of fancy by ascertained fact, thus furnishing a more correct and complete knowledge not only of its normal anatomy and physiology but also its pathology. In this connection it is interesting to note that, in the progress of medical science, it seems to be a constant fact that just in proportion as we gain exact knowledge of the anatomy and physiology of a part, does our knowledge of the symptoms which belong to its derangement increase and advance. Hence the trend of modern medical laboratory investigation is to associate symptoms with lesions, and this has been done to a remarkable degree of late, chiefly through the instrumentality of the microscope. In the diagnosis of nervous diseases, therefore, it is necessary to recognize the relative value and importance of the discoveries which recent laboratory investigations furnish, for it is by the practical utility of knowledge thus gained that we are supplied with a rational basis for the establishment of principles which govern the diagnosis of the several lesions, and in no portion of the nervous system is this found to be more true than in the spinal cord. If it be true, as already stated, that the prin-

*Read before the Tri-State Medical Association at Keokuk, Iowa, April 3, 1901.

ciples which govern the diagnosis of lesions of the cord are necessarily based upon the anatomy and physiology of the parts involved in the morbid process, it is hardly necessary to emphasize the extreme importance of their special study. Indeed, the diagnosis of such lesions presupposes a thorough knowledge on the part of the diagnostician of the histological details concerning the finer structure and function of the cord as well as its relation to other organs. With this in mind the physician or surgeon is well prepared to solve the many obscure problems in clinical neurology, and in fact reduce many of them to a matter simply of logical deduction. It is not the purpose of this paper, however, to enter into an extensive discussion of the technical details relating to the anatomy and physiology of the cord, as this can be found in the many excellent textbooks devoted to the subject. Moreover, time would not permit more than a hurried reference to a few of the more important anatomico-physiological considerations.

The cord consists of a long rod or tube of nervous matter extending from the foramen magnum to the second lumbar vertebra; two fissures in its median line almost completely divide it into two lateral symmetrical halves. Each half represents gray, white, and yellow tissue, each of which differs in appearance, structure, and physiological endowment. Generally speaking, the white matter surrounds the gray and corresponds to the nerve fibers, which are arranged in layers, masses, or columns. The gray tissue forms the most internal portion of the cord and corresponds to the cells, which are arranged in groups. They differ in size and diameter in different portions and are surrounded with the various histological units which comprise the neuron. The gelatinous or yellow tissue forms a cap on the posterior horn and differs from the rest by being composed of a translucent material, forming a fine network. Although it is developed from the same embryonic elements as the true nerve structure it has not the same nervous function and must therefore be regarded more in the light of a supporting structure. The fibers which make up the various tracts of the cord represented by the white matter are of two kinds, long and short. The long or projective fibers connect the different parts of the cord with the brain, and the posterior spinal ganglia with nuclei in the upper part of the cord. The short or association fibers connect different levels of the cord with each other, and also the two halves of the cord at the same level. Not all the tracts extend the entire length of the cord; for instance, the direct pyramidal terminates about the mid-dorsal region, while the crossed pyramidal extends the entire length of the cord. Taken as a whole the cord may be said to consist of a series of spinal segments or units placed one upon the other, each segment comprising that portion of the cord to which a pair of spinal nerves is attached. The segments vary in size in different regions. The spinal nerves have both a motor and a sensory root, which unite to form a complete physiological unit or circle of influence known as the reflex arc. There being thirty-one pairs of spinal nerves, so there are thirty-one segments as well as thirty-one reflex arcs, the whole comprising the spinal cord proper. Anatomically the segments consist chiefly of the white and gray matter already referred to, while physiologically they represent specific functional powers of a highly specialized character. Moreover each unit represents the origin of some, the extension and termination of certain other cells and fibers, together with other histological elements which go to complete their neuronic architecture. The correlation of all these anatomico-physiological elements in health constitutes the functions of the spinal cord. In this connection it is well to remember that each segment constitutes a center from which voluntary motor, reflex-motor, vasomotor, and trophic influences are distributed to, and to which peripheral impressions producing reflex movements and sensations proceed from a limited area of the body, viz., that portion to which the pair of spinal nerves is distributed. In addition each segment represents a conducting medium, through which the motor, sensory, inhibitory, and other tracts of fibers pass; these latter also connect the brain with all the segments of the cord as well as with the peripheral organs. In the diagnosis of any lesion affecting the cord, therefore, it is the disturbance of these various functions that constitutes the disease giving rise to special symptoms and which serves as a guide to their elucidation.

As the functions of the cord chiefly pertain to motor, sensory, reflex, and trophic mechanisms, a brief reference to their normal architecture may be in order.

Motor.—Motor impulses are discharged in obedience to the command of the will, by the generating motor centers on the cerebral cortex. The motor impulses thus liberated from the cortical cells are transmitted to their destination by means of the fibers which are the outgrowths of these cells and which constitute the great motor tract; this consists of the direct pyramidal tract or the column of Turk, and the crossed pyramidal tract of fibers. The column of Turk descends through the cord directly on the same side from which it is given off in the brain, while the crossed pyramidal tract partially or wholly decussates at the medulla, to terminate as does the direct tract in the large cells found in the anterior horn of the cord. From thence the fibers pass on to be ultimately distributed to the peripheral muscles. These two sets of fibers, taken collectively, therefore constitute the great motor tract or cerebrospinal system, which consists of medullated fibers whose function it is to control the voluntary movements of the body. The involuntary movements on the other hand are largely under the control of the sympathetic system, which consists chiefly of non-medullated nerve fibers, and they receive their innervation chiefly from the centers residing in the spinal cord. The functions of the cerebrospinal and sympathetic systems are normally more or less correlated, so that in morbid conditions of the cord the symptomatology of each is usually represented. Moreover it should be borne in mind that the motor tract can physiologically be divided into two portions, an upper cerebrospinal, and a lower spinomuscular portion, and the symptomatology of each differs materially. Hence, in estimating the relative value of symptoms, much depends upon the seat of the lesion, as on the character of its effects depend the symptoms. In addition to their control of voluntary movements, the fibers of the motor tract normally exert a continual inhibitory influence on the motor cells, so that when they are destroyed there develop spasmodic conditions of the paralyzed part.

Sensory.—In considering the sensory system, we find that the fibers which conduct sensory or afferent impressions enter and pass through either the lateral or posterior columns of the cord in various ways. The exact position which they occupy is not fully settled, but it is certain that each decussates at or about its point of entrance into the cord, this decussation being similar in character to that which occurs at the medulla with the motor fibers. After leaving the cord the main sensory tract passes through the medulla, pons, and other portions of the brain to terminate finally in the different sensory cerebral centers. The exact location of these also

is not as yet definitely settled, but much useful knowledge is already furnished in regard to their physiological effects that materially aids us in differential diagnosis. In a general way, the anterior and lateral ground fibers, as well as those of the lateral limiting layer, have the function of associating different levels of the cord and connecting them with nuclei in the medulla and centers in the cerebellum. The column of Gall conducts special sensations from the muscles, articulations, and tendinous sheaths through the root of the same side. When diseased there is a loss of the sense of position of the limbs, of the power of estimating weights, and of co-ordination of muscular effort, *i.e.*, ataxia. These fibers cross over in the medulla. The columns of Burdach conduct to a certain extent tactile sensation coming from the opposite posterior root. They also contain many associative fibers connecting different levels. Pain-sense fibers and excito-reflex fibers from the posterior roots run through these columns to reach the commissure of the anterior horns; hence, as Dana says, this is a pathway of all kinds of afferent impulses. When they are diseased there may be pain, anæsthesia, ataxia, and loss of reflex. The fibers of this tract cross over at once to opposite sides. The direct cerebellar tracts carry impulses to the cerebellum. The fibers originate in Clarke's cells and assist in maintaining the equilibrum. The antero-lateral ascending tract of Gowers conducts sensations of pain and temperature coming in from the opposite side through the anterior commissure.

Reflex.—As already stated, every segment of the cord represents an individual reflex arc. Peripheral irritation of all kinds often produces reflex movements in the muscular area to which the fibers of the anterior nerve root proceed. As a general proposition, the superficial reflexes are probably conducted by those fibers of the posterior foot which pass directly into the posterior horn of the gray matter, while the deep reflex impulses are probably carried by those fibers which pass through the post-external column. All observation tends to prove that reflex movements may be inhibited by an effort of the will, and that the fibers which control the inhibitory reflex probably pass down the cord in the crossed pyramidal tract. It is doubtful whether there are distinct inhibitory fibers, but it is quite possible that the same fibers that conduct voluntary motor impulses conduct inhibitory impulses also.

Automatic Centers (Dana).—The cord also represents centers which respond to certain stimuli, the action of which is purely automatic in character. They are the ciliospinal, secretory, vasomotor, genital, vesical, and rectal. These centers lie deep in the gray matter on either side of the central canal, but nearer the base of the posterior horn. The ciliospinal center extends from the seventh cervical to the second dorsal segment inclusive. Its stimulation causes the pupil to contract. The genital centers, including those for erection and ejaculation, reach from the first to the third sacral segment inclusive. The bladder and rectal centers are in the fourth and fifth sacral segments, the bladder being perhaps the lower. The spinal vasomotor centers extend from the second dorsal to the second lumbar segments. The vasodilator nerves, according to Gaskell, pass out by the anterior roots, while the constrictors pass out by the posterior. The fibers from the trophic centers for the joints, bones, and skin pass out by the posterior roots also.

Trophic.—It is a well established fact that the cells in the anterior horn exert a trophic influence on motor nerves supplying the muscles and that when these cells are destroyed the fibers arising from them undergo rapid degeneration while the muscle fiber atrophies. In addition, we know that the gray tissue exerts a trophic influence through the posterior root ganglia upon that portion of the skin to which the fibers arising from them pass, hence injuries to these parts produce a liability to rapidly developing bed sores. Moreover the direct and crossed pyramidal fibers of the motor tract have their trophic center in the motor area of the cerebral cortex. Lesions which sever this connection, therefore, are followed by descending degeneration of the pyramidal tracts in all segments below their seat. Moreover the fibers of the posterior nerve roots and their upward prolongations have their trophic centers in the posterior root ganglia. Lesions which sever their connection will be followed by ascending degeneration.

From the foregoing anatomico-physiological summary it follows that, in the clinical examination of persons suffering from diseases of the cord, it is necessary to recognize the specific functional endowment of each separate spinal segment, its relation to the spinal processes, its blood supply, together with the character of the symptoms expressed by its derangement, consisting in the loss of some and exaltation and perversion of others. Clinically they may be classified into those affecting the motor sensory, reflex, trophic, and visceral functions.

As the diagnosis of the seat of the lesion, as well as of its nature and character, involves the two most important problems in every diagnosis, it follows as logical sequence that the principles that apply in its solution elsewhere apply also in the case of disease of the spinal cord. It is scarcely necessary to repeat therefore that they are based upon a thorough knowledge of the functions of each individual segment of the cord, together with ability to interpret correctly the nature and character of the symptoms expressed by their derangement; this largely depends upon their mode of onset and duration, taken in connection with other facts pertaining to the family, personal, and clinical history of the case. When we come to consider specifically the diseases of the spinal cord we find the lesions producing them are even more limited than those of the brain, as already shown in a former paper. (See "Principles of Diagnosis of Lesions of the Brain," by the author, in the *New England Medical Monthly*, February, 1901)." Indeed they are comparatively few in number, while their effects vary greatly in character. Vascular lesions, for instance, we are told by Gowers, are very uncertain in the production of symptoms, hence such conditions as anæmia and hyperæmia, or even hemorrhage of the cord, are exceedingly difficult to demonstrate or recognize. New growths or tumors of the cord are extremely rare, so that the most common and consequently the more important diseases of the cord are those due to inflammatory and degenerative processes. The diseases which they produce, while clinically presenting a wide range of variability, consist chiefly of the different forms of meningitis, myelitis, and neuritis, primarily, together with their secondary effects, resulting in the various kinds of sclerosis, as seen in tabes and lateral sclerosis, besides the atrophies, dystrophies, and paralytic states. In this connection it must not be forgotten that the cord is liable to suffer not only from lesions that primarily affect the nerve elements proper, but also from those secondary influences that begin outside them, as, for instance, compression of the cord due to new growths or tumors, inflammatory products, or even hemorrhage. These conditions often determine degenerative and sclerotic secondary changes, giving rise to many symptoms

in common, but to others in particular that denote their special seat and nature. Moreover, in some affections of the cord we find the lesions are strictly limited to definite physiological areas or tracts of fibers, while in others they have no such limitations, but are indiscriminate in their invasion and influence. The former of these are recognized as *systemic* diseases while the latter are known as *non-systemic*. Occasionally we find a combination of these conditions, but in the majority of cases the lesion is not limited in its pernicious sphere of influence. While it may be convenient to classify these two groups of lesions clinically into intra-medullary and extra-medullary, yet this implies restrictions which are not justified in fact, and the classification can be retained only as a matter of convenience. It is certain from what has already been said that the majority of the diseases of the cord are due to organic lesions that are readily demonstrable by modern methods of investigation and technique, while functional disorders are comparatively rare and when present play a very uncertain rôle in the production of symptoms, which only a thorough knowledge of the functions of the cord can differentiate. Deliberate exaggeration or imposture may be suspected when there is no evidence of organic disease and when there is some obvious inducement for deception, for patients frequently exaggerate their complaints, sometimes purposely to deceive, at other times more or less unconsciously. It may be stated as a principle that the facts which lead to a definite opinion of imposture are usually of a non-medical character, the deception in most cases being easily recognized, while in others the recognition is surrounded with some difficulties. In summarizing the various steps that constitute the principles of diagnosis of lesions of the cord, we find they can be arranged as follows:

1. Determine whether the symptoms are due to a lesion affecting the spinal cord by reference to your knowledge of the function of its several parts, thus excluding those symptoms due purely to cerebral or peripheral lesions.

2. Next determine whether the symptoms are due to an organic or to a functional lesion, or are simply produced by malingering. This can usually be done by careful methodical examination of all parts involved in the process, together with a study of the mode of onset of the symptoms, their duration, nature, and character, and other facts connected with the family, personal, and clinical history of the case.

3. Next determine the exact location of the lesion, whether it be extra-medullary, intra-medullary, systemic, or non-systemic in its invasion. This calls for ability to interpret correctly the nature and character of the symptoms produced by these lesions, taken in conjunction with their causes and the known liability of certain structures to such lesions.

4. When all these questions are correctly answered we are then prepared to make our diagnosis, and upon this the prognosis and treatment are based.

In concluding I desire to acknowledge my indebtedness to such authors as Dana, Gowers, Bramwell, Berkely, and many others, whose works I have consulted and freely quoted, beside culling from recent literature.

Aldman Building.

The Cost of a Hospital Patient.—A French statistician has found the average daily cost of a hospital patient to be three francs seventy centimes (about seventy cents), divided as follows: Administration, .08; repairs on buildings, .17; heat and light, .32; materials, .54; food, 1.20; medical treatment, 1.16; sundries, .23.

CEREBRAL ABSCESS; OPERATION, RECOVERY.*

By FLETCHER GARDNER, M.D.,
BLOOMINGTON, INDIANA.

F. A. W., aged twenty-one, was referred to me on March 21, 1901, by Dr. P. C. Holland.

Family History.—His father died of consumption when the patient was three months old. A sister died of "brain fever" (cerebro-spinal meningitis), at about four years of age. The family history was otherwise negative.

Personal History.—The left ear has suppurated almost constantly since the patient was four weeks old. He has not been free from ear trouble more than two years altogether in his entire life. He has been subject to "fits of acute indigestion" lasting a day or two, and accompanied by constipation or diarrhœa and vomiting. With this exception he has been ordinarily well and has taken great interest in athletic sports.

Status Præsens.—March 21, 1901. The patient is a pale, rather slender, anæmic young man of medium height. On inspection the left tympanic membrane appears as a grayish, thickened, opaque curtain with a perforation in the upper anterior quadrant from which pus is exuding slowly. The external canal is red but not much swollen. The patient hears the watch at one inch or less. There is slight tenderness over the mastoid.

The ear was thoroughly washed out with hydrogen dioxide and at the next sitting a paracentesis was done in the lower posterior quadrant with a view to improve the drainage. An ice-bag was ordered over the mastoid and a brisk cathartic was given. The temperature at this time was only slightly elevated. After forty-eight hours' conscientious use of these measures, as the patient was complaining of pain in the mastoid and left eyebrow, and was evidently becoming somnolent and stupid, and had a temperature of 103° to 104°, an operation was decided on and done on the morning of March 24th.

Operation.—Assisted by Drs. John F. Potts and Lucy W. Gardner. I opened the mastoid, doing a Schwartze-Stacke exenteration, removing the contents of the middle ear, the posterior wall of the meatus, and the whole of the mastoid except the tip. The outer wall of the mastoid was at least a quarter of an inch thick and very hard. The inner portion was soft and easily removed with the sharp spoon. One or two cholesteatomatous masses were found and one suppurating focus.

The cavity was packed with iodoform gauze and the patient was put to bed. He reacted excellently and twenty-four hours later had a temperature of 99° with a pulse of 84.

The stitches were removed ninety-six hours after the operation. A small stitch abscess was found which healed without trouble but was held accountable for a temperature of 100°.

With the subsidence of fever following the operation a paraphasia affecting principally nouns became noticeable. Words were misused according to similarity in sound or meaning. For instance "doctor" became "lobster," the patients' temples became "houses," and he employed periphrastic expressions to avoid the use of nouns. At this time there was nearly complete word and letter blindness and complete agraphia. The axillary temperature remained at $98^{2}{}_{5}$° with unimportant variations, and the pulse fluctuated between sixty (during sleep) and eighty-four. On April 2d the paraphasia which had

* Read before the Lawrence County (Indiana) Medical Society, May, 1901.

seemed to be clearing up increased slightly, but the temperature was normal and the pulse seventy-two.

On the morning of April 3d I had Dr. Holland see him with me. At this time the aphasia was nearly complete, almost the only utterance being "picture, picture" in a drawling tone. The temperature was normal, the pulse fifty to sixty. The patient had ptosis of the left eyelid, slight paresis

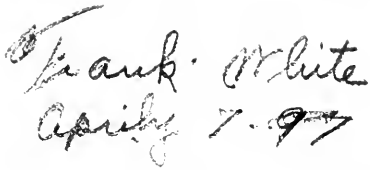

Fig. 1.—Signature of Patient Ninety Hours after Evacuation of Abscess.

of the right foot, and deviation of the tongue to the right. He was able to read one or two short words. When asked to write his name he made only the first stroke of "F." Tenderness was not found either on pressure or percussion anywhere over the head. He complained of severe pain over the right eye, in the eye, and at the root of the nose. The breath was very foul. There was no word-deafness at any time. An operation for abscess was decided on and was performed that afternoon, the more hastily because pressure symptoms were increasing. The operation was done by myself assisted by Drs. Holland, Potts, and Lucy W. Gardner. The first few minutes of anæsthesia caused considerable alarm, but strychnine was administered freely and ether was substituted for chloroform, and the operation was proceeded with as rapidly as possible.

A large flap was turned back with the base down, and the trephine pin was placed one and a quarter inches behind and the same distance above the external auditory meatus. As soon as the button of bone was removed the brain bulged into the opening without pulsating.

A grooved director was immediately passed through an opening in the dura in the direction of the ala of the opposite nostril. This line is the axis of the temporosphenoidal lobe and is most apt to pass through an abscess, when one of any size exists in that part of the brain.

The first thrust at a depth of one-half inch opened into an extremely foul collection of pus estimated at two ounces in quantity. The cavity was washed out with a hot boric-acid solution and a rubber tube about one and a half inches in length and three-sixteenths inch in caliber was passed through a button hole in the scalp and secured by a stitch. The scalp flap was stitched fast all round. A voluminous bichloride dressing was applied and the patient was put to bed. The operation proper occupied about thirty-five minutes. At the end of eight and of eighteen hours afterwards the dressings were changed, being wet with offensive pus and serum. Eighteen hours after the operation the patient asked for food, answered several questions rationally, asked to have his hands washed, and so on.

Ninety hours after the operation the motor aphasia was much improved, although he still called flowers "pictures." He wrote his name correctly (see figure 1) but could not read it when written. Word blindness was nearly complete but the young man recognized a few single letters and short words such as "and," "the," "our." The stitches were removed this time.

Five days after the operation, I examined him with Dr. Ernest H. Lindley, professor of psychology at Indiana University. We found the visual field slightly contracted, color sense normal according to the Holmgren wool tests; letter blindness, except for "E;" any uncertain letter was called, "W;" "and," "will," "the," "pay," were recognized in the newspaper. Of the sentence "and the boy ran" in script he recognized only "and the," but with slight prompting he recognized the other words and spelled out "ran." He wrote his name partly but desisted on account of fatigue.

The rubber drain was shortened on the seventh day, and removed entirely on the tenth day, gauze being substituted. The gauze was removed on the thirteenth day. From the tenth day on the man was able to sit up. The axillary temperature was never higher than 99° after the second operation.

The later history of the case is one of steady progress. The patient has gradually added new words and names to his vocabulary and new words in reading and writing. At present, three and a half months after operation, he is entirely well. He reads and writes perfectly and his speech would not be recognized as abnormal by any one unacquainted with his history.

The localization and diagnosis of this case before operation were very difficult. We had nothing definite

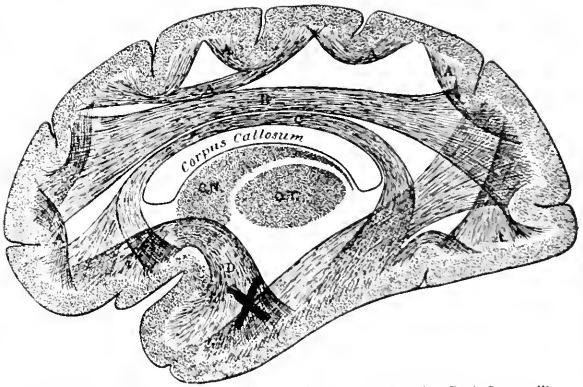

Fig. 2.—The Association Fibers in the Centrum Ovale (from Starr's "Brain Surgery"). A, between adjacent convolutions; B, between frontal and occipital lobes; C, between frontal and temporal lobes, the cingulum; D, between temporal and frontal lobes—lesion of this tract causes paraphasia; E, between occipital and temporal lobes—lesion of this tract causes word-blindness; CN, caudate nucleus, OT, optic thalamus; X indicates the seat of lesion in the present case.

except the aphasic group of symptoms to go on. There were (1) motor aphasia, (2) alexia, and (3) agraphia, more complete than either of the first two; there was no paralysis anywhere till just before the operation; there were no pressure symptoms until immediately before, when a fall in temperature and pulse took place (pulse 60 and 56, temperature 97°), and epileptiform convulsions occurred; there was little pain, and that located in the eye, and there was no tenderness on pressure or percussion.

The surface localizations of these centers are quite wide apart, and it is only since the operation that I have found the key to this, which is the fact that from the temporal lobe proceeds to the frontal lobe a band of association fibres, which have to do with speech, and any lesion of which causes paraphasia. A second band proceeds to the occipital lobe and a lesion of this causes alexia. It is probable that the agraphia, total aphasia, ptosis, etc., were pressure symptoms entirely.

The only author, of a large number whose works I have examined either in full or in abstract, who mentions lesions of the association tracts is M. Allen Starr,

and he does so both in his text-book on "Brain Surgery" and in an article published in the MEDICAL RECORD of December 11, 1897.

With these symptoms I thought it best to trephine at the point mentioned, and expected to explore the cerebellum through an extension downward and backward if necessary, and to trephine over the frontal lobes and the speech center if unsuccessful in my first attempt. Fortunately the abscess was easily found, and as easily drained, so that a more prolonged operation was unnecessary.

The surgical moral is that aphasia in the presence of ear disease calls for exploratory trephining. The neurological moral is that more emphasis should be placed on subcortical aphasia in teaching and writing.

As before mentioned the pus found in this abscess was excessively foul, having an odor like that of a decomposing cadaver. On several occasions bubbles of gas were seen to issue from the drain. Bacteriological examination of the pus taken sixty-six hours after operation showed a diplococcus, which was probably the prime cause of the trouble, and a new or rare bacillus, having an end spore like the tetanus bacillus, but the whole organism was much smaller. This bacillus forms a gas of most obnoxious odor. The identification has not been completely carried out, but the bacillus presents affinities with a saprophytic form isolated by Pasteur from a cadaver.

LIMITATIONS OF SURGICAL WORK FOR THE INSANE.*

BY WILLIAM J. MAYO, A.M., M.D.,
ROCHESTER, MINN.
SURGEON TO ST. MARY'S HOSPITAL.

MODERN civilization demands that the surgical diseases of the insane shall be as carefully treated as those of persons of sound mind. The successful invasion of the cavities of the body by the surgeon has stimulated attempts at operative relief for some of the more or less important phenomena which accompany insanity, and it is worth our while to go over the field occasionally and see to what end the efforts have led and to what extent they have been beneficial. For the past eighteen years I have had the privilege of operating upon the inmates of the Rochester Minnesota State Hospital for the Insane and for eight years at the St. Peter Minnesota State Hospital for the Insane. This work has been done under the general direction of the Superintendents, Dr. A. F. Kilbourne and Dr. H. A. Tomlinson. These hospitals have a total capacity of more than 2,200 inmates, and the opportunities for observation have been good.

In the earlier years of my acquaintance with the care of this class of patients, the asylum idea was predominant. The primary object was to prevent these unfortunate wards of the State from injuring others and, if possible, themselves, and this to be done as cheaply as possible. The surgery was that of dire necessity, such as operation for strangulated hernia, the results of traumatism, and malignant disease. Inadequate nursing facilities added to the difficulties to be encountered, and it must be admitted that surgery itself was in the transitional period between the "laudable pus" and the antiseptic eras. The results, taken as a whole, were not encouraging. The advent of the hospital idea with its trained nurse and skillful care, coming as it did with the enlarging field of modern surgery, gave tremendous impetus toward progress, and the hospitals for the insane of to-day are well managed in this respect. The surgical possibilities have increased in a corresponding ratio, with most gratifying results. This is true as to the physical infirmities of the insane; but has this improvement manifested itself, surgically speaking, in the cure or marked betterment of the mental condition? Mental instability is aggravated by physical disease and modified by its cure, but insanity itself does not often lie within reach of the surgeon's knife. The layman usually, and the physician too often, seems to think that the forty to fifty ounces of brain substance would functionate properly if it were not for a reflex impulse having its origin in some physical ailment in another part of the body. If the victim happens to be a woman the source is promptly traced to the generative organs. From the standpoint of the alienist, the most important factor is the predisposition of the patient, and upon tracing the histories of even those cases in which traumatism seems to have been the one important feature, the number of cases in which hereditary predisposition to unsound mind exists is nearly equal to the average of the so-called "idiopathic" cases. Disease or traumatism may be the immediate exciting cause, but the inherited mental instability is the essential etiological factor, without which the mental defect would probably not have appeared.

The writer does not possess special knowledge as to the general subject of insanity. The work which has been performed has been purely surgical, but it has extended over a period of time long enough to allow the ultimate result on the physical and mental condition of the patient to become apparent. From a scientific point of view it is absurd to speak of insanity as though it were a malady of fixed proportions, and an opinion drawn from such an indefinite picture of mental disease is of little value. To say that an operation restored to the normal the mentality of an insane person without detailing the exact nature of the brain lesion does not convey much information. We do not expect that relief from a physical ailment will greatly benefit the mental condition of an individual suffering from chronic dementia, although it might aid recovery from acute melancholia. The influence of an operation upon the mental symptoms of an insane individual depends more on the nature of the insanity than upon the surgical procedure which has been performed.

For the purpose of study, the indications for the surgical treatment of the insane may be divided into three general classes. First, the surgical relief of physical ailments without regard to the mental condition; second, operations for the purpose of relieving the mental condition of the patient; third, operations performed with the public welfare in view.

As to the first class there can be no question regarding the wisdom of giving to the insane the greatest possible relief from the suffering or discomfort of physical infirmity, and this without regard to the mental condition. It is a common experience to see an amelioration of the mental symptoms follow the cure of a hernial protrusion or the removal of a cataract. It can be stated, without fear of successful contradiction, that this improvement does not depend on the location of the disability. I have seen as much relief follow the removal of hæmorrhoids as after the repair of lacerations of the cervix and perineum. For the past eight years in both institutions an attempt has been made to perform a radical operation for the cure of hernia in patients otherwise in good condition. The necessity for this is obvious. The insane, by reason of their infirmity, are incapable of wearing a mechanical appliance for retention of the protrusion, and strangulations were, previously, frequent and often fatal. In the past

*Read by invitation before the American Medico-Psychological Association at Milwaukee, June 11, 1901.

four years some attempt has been made toward the operative relief of prostatic hypertrophies, and a few operations have been performed with fair results. In many wards, especially male, the smell of decomposing urine is present in spite of the best of ventilation. The cause usually lies in the mental condition of the patient, and is covered by the term: "filthy habits," but a certain proportion of these unfortunates are the subject of lesions of the urinary apparatus, which are amenable to surgical relief. Under the direction of the Superintendents a careful physical examination has been instituted among this class of the insane with a view to bettering their condition when possible. The number of prostatic hypertrophies did not prove as large as expected, perhaps not greater than among the sane of the same age, yet the relief afforded has been well worth the effort. I would suggest that urinary disturbance be made a cause of special examination with a view to ascertaining if there be a physical disability, and that prostatic hypertrophy, calculus, stricture, etc., should be considered surgically. Gallstone disease is frequent among the inmates, ten per cent. of the autopsies showing biliary calculi. Not all of these patients present marked symptoms, but a considerable percentage suffer greatly, and they should be relieved, other things being equal, by operation. The cases we have operated upon have been most satisfactory. Acute or chronic gastric distress should call attention to the possibility of gallstones, and repeated examinations made to detect their existence. Diseases of the genital organs in the male, such as phimosis, hydrocele, and occasionally, a symptom producing varicocele, may need operative treatment. Diseases peculiar to the female are common; uterine and ovarian tumors, retroversions, accompanied by inflammatory symptoms, lacerations of the cervix and perineum, etc., all demand attention and, in properly selected cases, should be surgically treated.

A large number of cataracts are to be found among the insane and they should be removed. These few common indications for operative interference are but examples of the immense field for surgery in which its good results cannot be questioned. The patient has a right to the largest measure of relief which can be given, and our duty is not finished when we have fed and clothed him well; this is important, but not enough. Surgery offers much to the sane, and mental disease should increase rather than diminish our efforts in behalf of its victims.

The second group of cases in which operation is undertaken for the relief of the mental condition of the patient has but a limited sphere of usefulness and the enthusiastic claims of the few are more than counterbalanced by the experience of the many. Traumatic epilepsy and insanity following injury certainly would seem to be the type most fruitful of surgical results. Generally speaking, cure of traumatic epilepsy follows in only four per cent. of cases operated upon, and of these the number in which cure has followed operation when more than two years have elapsed since the beginning of the epilepsy is exceedingly small, and few epileptics are admitted to the hospitals for the insane within two years of the beginning of the epileptic seizures. The predisposition, as manifested in the family history of those who became insane from this cause, is usually too marked to allow of much hope of cure, even if undertaken early.

In a considerable operative experience in traumatic epilepsies and periodical attacks of insanity from the same cause, I have seen but two cases in which relief was marked and lasted long enough to deserve attention. In neither case was there a return of the mental vigor, but in both there was amelioration of the periodical outbreaks, and both cases remain sufficiently well to warrant home treatment now for more than three years. These cases were not cured, but benefited.

The hopeless outlook may lead both the alienist and the surgeon to consider operative attack, and in suitable cases it is not only warranted but commendatory. The lesson to be learned from past experience is that a more careful selection must be made for operative treatment. The surgical cure of insanity, supposed to be due to a reflex irritation in a distant organ, needs but little discussion. The cases are usually reported early or the mental condition is greatly exaggerated, and the future progress seldom justifies the early prospects. The most energetic work along this line has been done by the gynæcologist. In an extensive experience we have seen few, if any, cures brought about in this way, but much relief in suitable cases. The insane woman suffering from disease or injury of the generative organs should be relieved surgically, not because she is insane, but because she has physical disease. The proposition that the diseased condition should be removed because the patient is insane and would not need operation if she were of sound mind is not tenable, and cannot be justified by ultimate result. Asylums of any size for the insane will usually contain a considerable number of women whose ovaries have been removed in the vain hope that cure of the mental disturbance would result, and too often the operation but aggravates the condition. The removal of the clitoris to prevent masturbation and in this way cure insanity had its advocates at one time. Fortunately this distorted view of the nature of mental disease has passed away, and while other misconceptions as to cause and effect have taken its place, the combined experience of the alienist and surgeon renders such delusions short-lived.

Operations performed for the public welfare are of questionable propriety, and at the present time would not have legal sanction. Dr. A. J. Ochsner, in a paper read before the Chicago Medical Society, calls attention to the ease with which the vas deferens can be divided without danger to life and, by the local use of cocaine, painlessly. This would absolutely prevent propagation in men, and would not necessarily interfere with the physical use of the generative organs. Dr. Daniel Brower, in a general address before the American Medical Assoiation at the Columbus meeting, advocated the procedure, and he believes the public will eventually demand that some such measure shall be taken to prevent the insane and habitual criminals from continuing their kind. The heredity of psychological defects is more marked than that of physical deformities, and the position taken by Drs. Ochsner and Brower is logical.

An analogous operation in women would hazard life, and as insanity is not a crime but a misfortune, we would have no moral right to subject them to operation. At my request Drs. Tomlinson and Kilbourne caused to be prepared a short synopsis of one hundred surgical cases operated upon and especial attention has been given to the question of the effect on the mental condition of the patient. The cases were selected at random from a large number of operations and without any attempt to prove preconceived opinions. The patients chosen had a complete history with records of the mental and physical condition before operation, during convalescence and for a sufficient length of time thereafter. The examination includes sixty females and forty males. Of the females sixteen per cent were improved mentally more or less by the operation, and of the

males twelve per cent. In most cases the mental improvement was such as we would naturally expect from the physical relief afforded. The patient looked brighter and appeared more cheerful, and in a few cases, the restoration was sufficient to enable the patient's return to home life. Only one patient was discharged cured in this series. This was a case of acute depression in a man admitted to the St. Peter State Hospital, suffering from chronic appendicitis. The process became suppurative, and the improvement mentally and physically, after operation, was coincident. As an equal number of patients was chosen from each of two hospitals situated at some distance from one another, and as the proportion of mental improvement was nearly the same in each, a comparrtive table prepared by Dr. E. Z. Wanous, first assistant at the Rochester State Hospital, has considerable value.

The physical improvement was marked in nearly all the cases operated upon. The results however, do not justify the statements which have occasionally been made as to the influence of bodily disorders, especially those of the female generative organs, in the production of insanity. Surgery has done much for the physical comfort of the majority, benefited the mental condition of a few, but rarely has materially dontributed to a perfect restoration both mental and physical

In conclusion let me say that the insane, from a surgical standpoint, have the same right as the sane—no more, no less.

THE PRIMARY TREATMENT OF INFECTED WOUNDS WITH TINCTURE OF IODINE.

By CARL BECK, M.D.,
NEW YORK.

While the treatment of wounds made by the aseptic surgeon has nowadays reached a state of perfection which might nearly be called ideal, it is yet practically impossible thoroughly to disinfect a wound, in the common sense of the word, after infection has occurred.

Schimmelbusch (*Transactions of the XXII. and XXIII. German Surgical Congress*, Berlin, April 15, 1893, and April 18, 1894) went so far as to deny the possibility of disinfection, even though an antiseptic fluid was applied immediately after infection. He had used bichloride of mercury, carbolic acid, lysol, acetate of aluminum, chloride of zinc, and caustics like nitric and acetic acids, without seeing the slightest effect. These solutions, even if they could be borne in full strength, did not seem to permeate the tissues invaded by the bacteria. Wound products containing albumin combined with the antiseptic solution, thus weakening or annulling its influence. This result seemed to show that the bacteria permeate the tissues very rapidly and get beyond the reach of antiseptic liquids. Five minutes after the introduction of pathogenic as well as non-pathogenic bacteria into fresh wounds, some of the internal viscera contained them. The experiments of Schimmelbusch, consisting in the inoculation of anthrax-bacilli at the distal end of a mouse's tail, are well known. No matter what the kind and strength of the disinfecting agent used immediately after inoculation, mice so treated died of sepsis, except when the tail was amputated within at most five minutes after infection.

Richter found the bacillus anthracis in the lungs, kidneys, liver, and spleen half an hour after inoculation.

Fortunately, these experiments do not, as a rule, correspond entirely to the conditions found in surgical practice, because they were made with the pure cultures of highly virulent bacteria, while our patients are ordinarily not inoculated with pure cultures of that bacterial species, and clinical experience has taught us that much can be done in infected wounds, especially by mechanical means.

So Henle (*Transactions of the XXIII. German Surgical Congress*) claimed that he was well able to disinfect wounds inflicted upon rabbits' ears and infected with streptococci, with solutions of bichloride of mercury 1:1000 and carbolic acid 1:100 applied two hours after inoculation. When applied six hours afterwards, disinfection was imperfect, but the severity of the infection was considerably diminished.

In view of these facts, it became a surgical axiom to rely more upon combined bactericidal measures than upon a single antiseptic drug.

The inability to combat directly the invasion of the enemy suggested indirect means of attacking it. If a position cannot be taken by storm, the enemy must be starved out. In order to accomplish this, the supplies must be cut off first—in other words, the soil that nourishes the bacteria and offers shelter to them must be destroyed. Besides, there must be ways found to prevent their development and multiplication. This is accomplished especially by broad incisions, removal of mortifying or necrosed tissue, and the absorption of the wound secretion by gauze, preferably iodoform gauze.

Of course, a drug which would penetrate the deeper layers of the infected tissue, as the Roentgen rays do, for instance, is a great desideratum. The latter exert, as experiments have shown, a disinfecting influence if a strong current is used, but, in the present form, their practical utilization meets with too many difficulties.

As I have emphasized previously (see my book on fractures, page 199), the tincture of iodine is an antiseptic which, to some extent, possesses a permeating power. It was originally used only for the disinfection of the skin and the deep-skin bacteria, but I have also tried to use it methodically in all infected wounds. Practically all wounds which are not inflicted by the aseptic surgeon on an aseptic field are to be regarded as infected.

The tincture was liberally applied once over the carefully dried wound-surface. Fifteen minutes afterwards, examination of the tissues showed the evidence of permeation, and no cultures could be obtained from such areas. While this does not prove that bacteria were destroyed in these regions, it can be assumed that the soil was rendered unfavorable for their further development.

No general disturbance has yet been observed in the large number of patients in whom the iodine treatment has been tried, although in two cases iodine reaction was found in the urine three and four hours after the application. The further treatment was carried out on general principles. All the cases treated in this manner ran a favorable course.

Further observations will be reported later.

Persistent or Cyclic Albuminuria without Clinical Symptoms.—G. E. Tyler says that in order to reach a diagnosis the following things are necessary: 1. The demonstration of a persistently intermittent albuminuria unaccompanied by casts or other evidence of renal disease. 2. The elimination of diseases of other organs, especially of a left ventricular hypertrophy. The condition is probably harmless, though some assert that it always means ultimate organic change. No medicines have any effect on the condition. A well-regulated life, free from all excesses, is the best treatment.—*Denver Medical Times.*

Auscultation of the Mastoid.—J. A. H. Andrews advises the use of the stethoscope and tuning fork in examining mastoid cases. The test for the density of the mastoid is made by using a stethoscope with a small bell over the tip and placing the handle of a vibrating tuning-fork against the mastoid in the neighborhood of the antrum. It is found that when the mastoid cells are filled with pus or granulations, or when the density is increased from bone proliferation, the sound waves are transmitted to the ears of the examiner with greater intensity and for a longer time than when the stethoscope and tuning-fork are placed in the same relative position over the opposite or a normal mastoid. In the examination of the two hundred mastoids in which there was no history of disease the following results were obtained: (1) The length of time in which the fork could be heard over apparently normal mastoids varied from fifteen to twenty-two seconds. (2) The average length of time the fork could be heard was about eighteen seconds; (3) The length of time the patient could hear the fork by bone conduction was, as a rule, slightly less than the time the surgeon could hear it with the stethoscope, *i. e.* bone conduction was slightly less than auscultation. (4) If the conducting properties of the stethoscope are greater than the conducting properties of the one used the difference between bone conduction and auscultation will be increased, while if the conducting properties of the stethoscope should happen to be less the relation between bone conduction and auscultation may be reversed; (5) Tuning-forks vary greatly in the time they can be heard by the normal ear. The principles underlying the method and upon which conclusions have been based are: (1) The greater the density of the medium, the greater will be its sound-conducting property; (2) The more nearly uniform the medium, the greater will be its sound-conducting property; (3) Solid media of the same density transmit sound waves, within certain limitations, in proportion to their relative thickness.—*The Laryngoscope.*

Tuberculosis in Cattle.—J. P. Penberthy believes that the main factor in causing tuberculosis in dairy cows is the congregating of the animals for a long period indoors. Sheep leading a life in the open air are very rarely affected. Cows in mild climates, such as Jersey, where housing is little followed, enjoy comparative if not complete freedom. In fact, overcrowding with bad ventilation and lack of sunlight is accountable for a large percentage of cases. But all these bad conditions alone are not sufficient for the development of the disease. There must be the exciting factor, the specific microbe which is introduced by an infected animal. Hence the necessity for removing diseased cattle from the herd, and the careful inspection of meat and milk, in order to prevent the spreading of the malady in mankind. The necessity of careful inspection is all the more evident when it is remembered that the general effect of the tubercle germ on the constitution of the animal affected, apart from the destruction of the portion it invaded, is usually marvellously little. It is not uncommon to find the most extensive tuberculosis in cattle in apparently prime condition and perfect health. It will be thus seen that the flesh of animals might contain the germ, and as it is a truism "that any man or animal taking the tubercle bacillus into his system runs a risk of becoming tuberculous," there is a certain amount of danger associated with the consumption of flesh from tuberculous animals.—*Medical Press and Circular.*

The Influence of the Climate of Colorado on the Nervous System in Health and Disease. J. T. Eskridge says that in health, and with the unacclimated, no unpleasant effects are experienced from the altitude, provided the newcomer does not over-exercise. Mentally and physically he is stimulated. If over-exercise is indulged in, the muscles speedily become sore and are affected by cramps, while sleeplessness follows. Under normal conditions sleep is refreshing. Women, especially those of a nervous temperament, are apt to become distinctly hysterical. Irritability and peevishness are not uncommon. The process of acclimatization for healthy individuals is short and simple. Many seem to experience no inconvenience from the altitude, although they exercise from the first day of their arrival in Colorado and begin to ascend high altitudes.

In regard to climatic effect on the nervous system in disease the author reminds us that most health-seekers who come to Colorado are suffering from tuberculosis of the lungs. Many nervous and mental disturbances frequently develop during the course of this disease. The most prominent of these are insomnia, nervous irritability, mental depression, sometimes amounting to melancholia with suicidal tendencies, and meningitis. Insomnia is generally relieved if the case is one the tuberculous features of which are favorably affected. Nervous irritability is often almost entirely thrown off. Mental depression among tuberculous cases is more common than at sea-level. Many factors, such as absence from home, etc., enter into this question entirely apart from climate. Hysterical patients do better at sea-level, and the same may be said of neurasthenics, choreics, sufferers from sick headache, epileptics, and the nervous and impressionable in general.—*Denver Medical Times.*

The "Monoma."—Herbert Snow calls attention to the existence of a progressive and malignant growth, for which he proposes the new term "monoma." It is important that it should be differentiated from the comparatively harmless myoma by this or some other distinctive word. The disease is malignant, and if once recognized should be immediately removed, but the important question of diagnosis is as yet unsettled. The presence or absence of vaginal hemorrhage, as insisted on by Lawson Tait, is untrustworthy. With that event alcoholic habits have much to do. If we encounter a solitary, rounded, doughy central uterine tumor which is growing rapidly, while the patient is losing weight, if we find an indistinct fluctuation so that we wonder whether it may be an ovarian cyst, and if there has been much recent trouble and anxiety, then the author holds that we are justified in diagnosing a monoma and in advising prompt excision.—*Medical Press and Circular.*

Remarks on the Summer Diarrhœa of Infants.—J. D. Windle holds that bottle-fed children are especially thirsty in summer because they are usually given their food as concentrated as in cold weather. They take the bottle ravenously and so get over-fed. By the diarrhœa, vomiting, and perspiration the amount of water lost is out of all proportion to that taken in, and thirst causes the restlessness wrongly attributed to physical pain. The indications are to stop food and stimulants, and give cold boiled water as much and as often as the child may take. It may object to the first teaspoonful, but is greedy for the remainder. This exclusive water diet may be continued for forty-eight hours with safety, but is rarely required longer than twelve or twenty-four. Tepid sponging if there is fever, hot dry packs if there is collapse, large linseed-meal poultices to cover the abdomen if there is pain, are valuable auxiliaries.—*The Clinical Journal.*

Idiopathic Peritonitis.—H. Nothnagel is of the opinion that the possibility of a true primary idiopathic peritonitis has not yet been demonstrated. Besides the portal through the female genitalia, the only way by which micro-organisms can directly reach the peritoneum from without is via the blood current, and this, the author believes, never takes place. Even in cases in which the tonsils are taken as the sites of the infection, it is more likely that the bacteria, in consequence of enteric processes, pass through the intestinal wall. The great power of absorption possessed by this serous membrane is another safeguard which, no doubt, is particularly active in preventing peritonitis in the acute infectious diseases.—*Wiener klinische Rundschau.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 3, 1901

THE STUDY OF PLAGUE IN MANILA.

SCARCELY has there been time for digesting the contents of Army Circular No. 2, on tropical diseases in the Philippines, when No. 3 appears, treating the subject of plague. As we remarked on a previous occasion, too much praise cannot be accorded to the admirable work being done in the army laboratories in Manila. The results show how much can be accomplished by governmental patronage for bacteriological work and by the systematic publication of the practical findings on given lines of investigation. Assistant Surgeon H. W. J. Calvert, U. S. A., makes this report.

Although much has been written recently on plague, there are many points regarding its bacteriology which are not so well understood as they might be. It becomes quite evident that the more we study the disease by modern methods, the more is it robbed of its terrors. The thoroughness with which the whole subject is treated in the present instance leaves hardly anything to be desired in making the practical deductions well up to date.

It is interesting to learn that the plague organism—the bacillus pestis bubonicæ (Kitasato)—is quite long-lived in dark places, having been recovered as late as the forty-fifth day, but that sunlight destroys it within three hours. It is also very easily killed by ordinary disinfectants and is very susceptible to heat.

From observations in the Manila laboratory it would appear that infection occurs mostly through abrasions of the skin or external mucous membrane. Contrary to the statements of many authorities, the alimentary canal appears to be a main port of entry for the bacillus. The infected breath in pneumonic cases, blood from the nose and lungs, menstrual flow, vomitus, fæces, secretions from pustules and carbuncles, and pus from buboes may each in their turn serve as media for direct infection. Clothing, exposed fabrics, or merchandise infected by dead rats, may also transmit the disease. The emigration of rats from district to district is also an important factor in the spreading of the plague.

The experiences in Manila are in accord with those in other places as to the gradual spread of the pest. Usually considerable time elapses between each case, and the disease may linger for two or three years before becoming epidemic. When once introduced, however, plague continues from year to year, with an occasional intermission of a year, for an indefinite period. The yearly prevalence of plague usually lasts but a few months, when it dwindles into sporadic cases of mild type. In the severe forms of seizure, the so-called septicæmic variety, death may occur within twenty-four hours after the onset. In the second week the fatal issue is due to secondary infections following extensive necrosis of the vital organs. In contrast to many other infectious ailments, one attack does not insure absolute immunity.

For convenience of pathological study the disease is classified as pestis minor, pestis bubonica, septicæmic plague, and pneumonic plague, the bubonic form being the most common. In respect to the particular lesions of each variety, nothing new has been noted.

The most important practical deductions from the studies in question bear upon prophylactic measures. An early diagnosis of the first cases is essential. Suspected cases should be isolated and closely observed, and those associated with them should be isolated in a detention camp for at least ten days. Unhygienic localities should be cleansed and disinfected. Burning of buildings is advocated as the surest of all methods of preventing the spread of the pest. Short of this radical measure, carbolic acid, bichloride of mercury, or any other cheap disinfectant may be used. The best disinfectant for clothing is steam. Those coming in direct contact with the disease are advised to disinfect the hands with carbolic acid or bichloride of mercury immediately after exposure; such precaution being founded on the bacteriological theory of skin infection.

Rigid quarantine regulations are very properly insisted upon, no passenger or animal being allowed to leave an infected port until after a detention of ten days.

The general treatment of plague is based on the usual indications for meeting a depressing disease, and it is advised merely to open bubonic abscesses rather than attempt to remove the glands. Protective inoculation does not find favor, as at best temporary protection only can be expected.

THE REDUCTION OF SHOULDER DISLOCATIONS.

So much has been written about dislocation of the shoulder-joint that it is not easy to invent a really new method of treatment, but the injury is so frequent and important that good suggestions should always be considered. F. Hofmeister, of Tübingen, has proposed in the *Beiträge zur klinischen Chirurgie Band XXX.*, September 2, 1901, a method which is practically new, although it is to a certain extent adapted and modified from older procedures. He reports seven cases, in all of which the method was successful, though in three instances the injury was more than eight days old.

The plan is very simple, and requires for its execution only a vertical extension apparatus and some weights, up to about twenty kilograms in aggregate. The patient is laid upon the uninjured side, and the injured arm is bandaged as high as the insertion of the deltoid, so as to secure a firm hold for the extension cord. The latter is passed over the pulley and a weight

of about five kilograms (eleven pounds) is attached. This, of course, holds the limb in complete vertical extension, and exerts a continuous pull against the muscles of the shoulder girdle. After a few minutes, more weight is added, and this process is kept up until the contraction of the muscles is overcome, and the head of the humerus is drawn to the edge of the glenoid fossa into which it either slips spontaneously or may be pushed very easily. The amount of time required for the success of the manœuvres varied from fifteen to forty-five minutes, and the weight from five to twenty kilograms. The advantages claimed are avoidance of anæsthesia, simplicity, and entire absence of danger.

The avoidance of anæsthesia is often of very great importance when we are dealing with such an injury as an uncomplicated dislocation, so that this point is in favor of the new method, especially when we remember that when the weights are attached, there are no painful manipulations to be carried out. In regard to simplicity, everyone is, of course, aware that nothing can be simpler than Kocher's method of dealing with the sub-coracoid displacements of the humerus, but Kocher's method is not always successful; it frequently requires an anæsthetic, and not uncommonly some extension method has to be substituted for it. The heel-in-axilla method also commonly requires an anæsthetic, both on account of pain and to secure the relaxation which is so important when the muscles are spasmodically contracted from the irritation of the injury. There is a certain small percentage of danger in the reduction of a dislocation under an anæsthetic, on account of the possibility of injury to nerves, tendons, blood vessels and even bones. With care, this percentage is exceedingly small, but it is claimed, with apparent justice, for this new method, that such dangers do not exist, and it is an advantage to avoid a percentage of danger, no matter how small. Such a vast majority of dislocations of the shoulder are either sub-glenoid or sub-coracoid, that in considering special methods the rarer forms may be disregarded, and for these ordinary forms this new method is well adapted, and worthy of trial. There seems to be no reason why the weight of twenty kilograms should not be exceeded, if necessary, especially in muscular patients, though it is the highest weight mentioned in the article which we have quoted.

THE FIGHT AGAINST TUBERCULOSIS.

THE statement made by Koch just before the meeting of the Congress on Tuberculosis in London last week, that the danger of acquiring tuberculosis through the milk of tuberculous cows is so slight that it may in practice be ignored, quite naturally excited considerable comment both in the daily press and among sanitarians and physicians generally. In the paper read subsequently before the Congress, and published in the current issue of the *Journal of the American Medical Association*, we find that this question does not occupy such an all-important place in the article as the cabled interview with the author had implied.

The paper begins with the argument that tuberculosis is a preventable disease, a fact, Koch says which ought to have become clear as soon as the tubercle bacillus was discovered, and of which he himself was fully aware from the moment he had made his famous discovery. He then says that no one system of preventive measures will apply to all pestilences, instancing the various means employed in the suppression of plague, cholera, hydrophobia, and leprosy, and that tuberculosis is no exception to this rule. The main source of infection in tuberculosis is the sputum, and others, such as heredity and the ingestion of milk or meat from diseased cattle, may practically be ignored in the fight against the disease in man. The experiments which he cites as disproving the liability of the transmission of tuberculosis from cattle to man are in every practical respect the same as those previously made by Theobald Smith in this country. Koch admits that he has been conducting these experiments only during the last two years; that is, Koch *began* his experiments in 1899. Theobald Smith *published* the results of his in the first half of 1898; yet Koch has the hardihood to say (italics ours): "Comparative investigations regarding human and bovine tuberculosis have been made *very recently* in North America by Smith, Dinwiddie, Frothingham, and Repp, *and their result agreed with ours*." It is a pity that a man who has done so much for science cannot be content with what he has really earned, without taking to himself credit for the prior discoveries of others.

The measures which Koch recommends for the suppression of tuberculosis are an increase in the number of hospitals specially devoted to the care and treatment of the subjects of established tuberculosis, notification, disinfection, and the education of the public regarding the infectiousness of the disease and the best means of protection against it. He expresses himself in favor of sanatoria for consumptives in the early stages of the disease, but warns his hearers "against an over-estimation of their importance which has recently been observable in various quarters, based apparently on the opinion that the war against tuberculosis can be waged by means of sanatoria alone, and that other measures are of subordinate value." In reality, he says, the contrary is the case.

The tone of Koch's article is one to give encouragement to all who are striving and hoping for the suppression of this scourge of mankind, and the author's conclusions are marked by an optimism which it is refreshing to note. "If now," he says, "in conclusion, we glance back once more to what has been done hitherto for the combating of tuberculosis, and forward to what has still to be done, we are at liberty to declare with a certain satisfaction that very promising beginnings have already been made. Among these I reckon the consumption hospitals of England, the legal regulations regarding notification in Norway and Saxony, the organization created by Biggs in New York—the study and imitation of which I most urgently recommend to all municipal sanitary authorities—the sanatoria, and the instruction of the people. All that is necessary is to go on developing these beginnings, to test and if possible to increase their influence on the diminution of tuberculosis, and wherever nothing has yet been done, to follow the examples set elsewhere." These are words of inspiration to all engaged in this modern crusade, and we can but hope that Koch himself will long be spared to aid in the combat (giving proper credit to his colleagues for their share in the struggle), and that he will live to

see the final victory which has been made possible by his glorious discovery of the bacillus tuberculosis.

HOSPITAL ADMINISTRATION.

THE bitter quarrel which has been pending for the past few years among the members of the medical staff of the National Hospital for the Paralyzed and Epileptic, in London, reached a crisis some months ago, and the public have had since that time ample opportunities to judge of the situation for themselves. Both parties to the controversy have aired their grievances in medical and lay journals, and it is the general opinion that it is now full time that the matter should be settled definitely, not only for this hospital, but for all others.

The burning question is, Should laymen wholly control hospitals, or should medical men have something to say with regard to the management? *The Practitioner* for June is entirely given up to a consideration of the subject and contains several contributions by men of note, medical and lay. All these writers, without an exception, express the opinion that it is essential to the successful management of a hospital that the medical staff should be represented on its governing body, although none advises that the ultimate control should be taken out of the hands of the non-professional element. In fact, the medical men are very modest in their demands, simply claiming that they should not be absolutely precluded from exercising a certain amount of influence in deliberations affecting the welfare of the institution to which they are attached.

As regards the specific case which gave occasion to the discussion, it is satisfactory to learn that a committee of inquiry chosen by the governors of the hospital have found the complaints of the medical staff justified, and as a result have recommended, among other things, that the staff be accorded the representation on the Board of Managers that it demanded as necessary for the welfare and successful administration of the affairs of the institution. Such representation, the report of the committee says, "would, beyond all other methods, secure the best and most satisfactory means of intercommunication between the staff and the medical board, and it would be to the great and permanent benefit of the hospital." The trouble arose largely from the officiousness and tactlessness of a layman, who was at once secretary and general director, and whose prototype, unfortunately, can easily be found in other institutions. The recommendation was made further that the position of general director be abolished, and that the members of the medical and resident staffs and their subordinates be independent of the authority of the secretary, but responsible to a resident medical superintendent, to be appointed. The entire report should go far to correct the opinion that seems to prevail in some quarters that hospital administration is a mere business matter for the conduct of which only laymen are qualified and medical men are especially disqualified.

The conclusions come to by the writers in *The Practitioner* that the practice of debarring medical men from taking a part in the management of hospitals is anomalous and absurd, will commend themselves to the medical profession of this country as eminently reasonable. It has been shown, in the case of many hospitals in this country as well as in Great Britain, that lay and medical members of the governing body can work together, without friction and to the good of all concerned, and it will be to the best interests of hospitals generally if such a course be pursued.

News of the Week.

The Tuberculosis Congress.—On Thursday afternoon, Earl Spencer, one of the vice-presidents of the Congress on Tuberculosis, severely criticised Koch's assertion that human beings are in no danger of contagion from tuberculous cattle. He said he hoped that it was true, but he hoped more that the dissemination of such views would not tend to cause laxity on the part of dairymen and cattle owners, or less vigilance by the authorities charged with protecting the consumers of milk. The speaker earnestly trusted that the congress would not indorse the heretical and at present unjustifiable statement that it was unnecessary to take measures to prevent the transmission of tuberculosis from animals to human beings. Prof. John MacFadyean read a paper on tubercle bacilli in milk in which he criticised Koch's views, contending that the grounds upon which the Berlin professor based his belief were either not well founded or had little bearing upon the question, and he asserted that the strongest grounds existed for regarding milk from tuberculous cows as distinctly dangerous to human beings. Dr. Ravenel, of Philadelphia, gave an instance of the infection of ten persons from tuberculous cattle, but said he considered such instances rare. Mr. James King, a London veterinary surgeon, dissented flatly from Koch's belief in the non-transmission of bovine tuberculosis to human beings, and urged the adoption of more stringent measures to prevent the sale of tuberculous meat and milk.

The closing session of the Congress was held on Friday under the presidency of the Earl of Derby. At this meeting resolutions were adopted recommending legislation toward the prohibition of expectoration in public places, the notification of the proper authorities in cases of phthisis, and the use of pocket spittoons. It was asserted that these sanitary provisions were indispensable in order to diminish tuberculosis. A resolution was also adopted expressing the opinion of the Congress that health officers should continue every effort to prevent the spread of tuberculosis through milk and meat. As, however, the question concerning human immunity from bovine tuberculosis was of vital importance to the public health and the agricultural interest of the country, it was urged that the Government immediately institute a rigid inquiry into the identity of human and bovine tuberculosis.

At a banquet given to the delegates in the evening, Dr. E. G. Janeway, of New York, responded, in behalf of his American colleagues, to the toast "Our Foreign Guests."

Increased Sickness among Children.—The trustees of St. John's Guild state that their floating hospitals are crowded with sick babies every day, as is also the Seaside Hospital on Staten Island, nearly ten thousand having been carried in one week. There are more cases of severe illness among the babies than have been known in the history of the guild. The Lewis Memorial Cottage, especially designed for the treatment of very ill babies, has not a single vacant bed, and applications for admission to the Floating and Seaside hospitals of very seriously sick babies are so numerous that some children with only slight summer complaints are perforce denied

admission. The Guild is making every effort possible to meet the unprecedented demand, but needs financial help, for which it has issued an appeal to the public. There can be little doubt that much of the increase in infantile disease this summer, as compared with previous summers, is due to the filthy condition of the streets of the city.

General Leonard Wood, who is convalescing from typhoid fever, arrived in New York on Tuesday of this week. He is still under the care of his physician, Major Dámaso T. Lainé, and will spend a few weeks cruising along the New England coast, returning to Havana as soon as his strength is fully restored.

Free Rides for Sick Children in St. Louis.—The St. Louis Transit Company has issued an order that, during the period of excessive heat, children ten years of age or under, and one member of the family whose parents are unable to pay transportation, will be permitted to ride free on the cars of the company to the various parks on presentation to the conductor of a doctor's certificate certifying that in his judgment they would be benefited by an outing.

Charges against a Coroner.—George W. Delap, a Coroner of Brooklyn Borough, was arrested a few days ago on the complaint of a detective of the District Attorney's office. The charge was that of bribery, a woman having reported that she had paid the Coroner money to have the death of her husband, who, as alleged, committed suicide, certified to as accidental. The arrest was informal, the accused being accompanied to court by his bondsman, who gave bail of $5,000 for his appearance at the formal examination.

The Yellow Fever Serum.—Dr. Bellinzaghi, who was in New York last winter endeavoring to organize a company for the manufacture and sale of his alleged specific for yellow fever, has gone to Havana with a Dr. Caldas, of Brazil, with the object of experimenting further with the serum. There have recently been a few cases of yellow fever in Santiago de las Vegas (not the large city of Santiago de Cuba), but there is no opportunity elsewhere on the island for the making of satisfactory tests, and it is probable that even this small outbreak will be over before the serum arrives. It is said another attempt will be made to organize a company to exploit the serum. But if yellow fever is to be abolished in Cuba, there will be little demand in this country for prophylactic inoculations.

Typhoid Fever is prevailing to an unusual extent in Chicago, eight deaths occurring on Saturday of last week. The entire week previous there were but thirteen deaths, and the week before that ten. On Sunday there were thirty-eight cases in the Cook County Hospital, an increase of seventeen cases in one week.

The San Juan de Dios Hospital in Manila.—The Philippine Commission has offered to purchase the San Juan de Dios Hospital, which is the only general hospital in Manila. The proposition is under consideration by the church authorities, to whom the building belongs. The Commission proposes to convert the hospital into a public institution, if it can be secured.

The Study of Cancer.—During the reception at Marlborough House of the foreign delegates to the Tuberculosis Congress, King Edward urged them to direct their attention as well to the study of malignant disease, saying, "God grant that before long you may be able to find a cure for cancer or check its course." This incident has revived the rumor that his sister, the Empress Frederick of Germany, who is again reported to be seriously ill, is suffering from cancer.

The Canadian Medical Association.—The annual meeting of this society will be held at Winnipeg on August 28, 29, 30 and 31. The address in surgery will be delivered by Dr. O. M. Jones, of Vancouver, and the address in medicine by Dr. J. R. Jones, of Winnipeg. The railroads have promised a single fare return rate, on the certificate plan. The General Secretary of the Association, from whom all information as to rates, excursions and scientific programme can be obtained, is Dr. F. N. G. Starr, Biological Building, Toronto.

The Wisconsin State Medical Society.—At the annual meeting of this society, held at Waukesha, June 26-28, under the presidency of Dr. J. F. Pritchard, of Manitowoc, the following officers were elected: *President*, Dr. W. H. Nielsen, of Milwaukee; *Vice-Presidents*, Drs. A. J. Hodgson, of Waukesha, and L. H. Pelton, of Waupaca; *Secretary*, Dr. C. S. Sheldon, of Madison; *Assistant Secretary*, Dr. A. T. Holbrook, of Milwaukee; *Treasurer*, Dr. S. S. Hall, of Ripon; *Censor*, Dr. Wallbridge, of Milwaukee. The meeting of the society in 1902 will be held at Milwaukee.

Medical Excursions are the fashion now on the Continent of Europe. They are organized much on the plan of the Cook's tours, the object of the excursionists being to visit and inspect the various spas and other health resorts. The French and the Germans are most addicted to the "bath-journey" habit, but the English are gradually acquiring it. Recently a party of thirty-two English physicians visited Nauheim. They were received by all the doctors of the place, headed by Professor Schott, and conducted to the Hotel Augusta Victoria, where a banquet and fête were given in their honor. On the day following they visited the springs and baths, where explanations were given by Drs. Schott, Grodel, Friedlaender and Greubner. In the evening they were entertained at the Kurhaus by the management.

The Fourteenth International Medical Congress will be held in Madrid, under the patronage of King Alfonso XIII. and his mother, the present Queen Regent, on April 23-30, 1903. The fee for membership in the congress is thirty pesetas ($6), which may be sent at any time prior to the opening of the congress to the Secretary-General, Dr. Angel Fernandez-Caro y Nouvilas, Madrid. The scientific work of the congress will be divided among the following sections: 1. Anatomy (including anthropology, comparative anatomy, embryology, descriptive anatomy, normal histology, and teratology); 2, physiology and biological physics and chemistry; 3, general pathology, pathological anatomy and bacteriology; 4, therapeutics, pharmacology, and materia medica; 5, internal medicine; 6, neurology, mental diseases, and criminal anthropology; 7, pediatrics; 8, dermatology and syphilography; 9, surgery; 10, ophthalmology; 11, otology, rhinology, and laryngology; 12, odontology; 13, obstetrics and gynecology; 14, military medicine and hygiene; 15, hygiene, epidemiology and sanitary science; 16, legal medicine. The ladies accompanying members will be entitled to reduction in railway fares and to participate in all the excursions and other entertainments given in honor of the members of the congress. In order to secure these privileges they must have a personal card, obtained on payment of a fee of twelve pesetas ($2.40). The executive committee of the congress is constituted as follows:

President, Prof. Julian Calleja y Sanchez; *Secretary-General*, Dr. Angel Fernandez-Caro y Nouvilas; *Treasurer*, Dr. José Gomez y Icaña; *Members*, the presidents and secretaries of the several sections.

A Medical Historical Museum.—Dr. Cabanès is about to establish in Paris a museum designed to show by books, pictures, instruments and prescriptions the exact state of medical science at different epochs in the world's history, and also the gradual progress made in the healing art through the ages.

The French Surgical Society.—The fourteenth annual meeting of the Association Française de Chirurgie will be held in Paris in the week beginning October 21. The subjects announced for the set discussions are "Surgery of the Spleen," to be opened by Dr. Ferrier of Nancy, and "Treatment of Tuberculous Adenitis," to be opened by Dr. A. Broca of Paris. The president of the Association is Dr. Lucas-Championnière of Paris.

The League against Seasickness, a French association, the laudable object of which is the study, with a view to prevention and cure, of naupathia, announces the first annual exposition of remedies against seasickness. The exposition will be held in August and September at Ostende, under the patronage of the King of Belgium. Among the exhibits will be suspensory appliances designed to reduce the movement of the cabins on ships, apparatus for immobilizing the viscera, methods for the aeration and regeneration of the air in cabins, remedies for seasickness, and the literature of the subject. Public trials of the various appliances and remedies will be made off the shore of Ostende. During the course of the exposition, a congress for the study of seasickness will be held at the same place. Those interested in the subject may obtain further information by addressing the "*Ligue contre le Mal de Mer*," 82, Boulevard Port-Royal, Paris.

A Collecting Agency and the Failure of Its Plans.—We noted a few weeks ago the attempt of an alleged collecting agency to obtain money from a number of Brooklyn physicians on the strength of a contract which the latter had inadvertently signed. As this agency is said to be working in other parts of the country, the following facts may be of interest and serve as a warning against the signing of any paper without a thorough understanding of its contents. The agent of an alleged collecting agency called upon a number of physicians, soliciting claims, especially old ones and those against parties who had removed from the State. There were two blanks to be signed by the physician, which he was led to suppose were duplicate contracts. The one given to him to read, and which was kept by him, was a very innocent paper, but the other was a hard and fast contract, in the form of a note, with so many requirements that it was practically impossible for any one to comply with all, and the breaking of any one of which made the physician liable for a considerable forfeit. The suits brought by the company against several physicians were decided in favor of the latter, on the ground that the company was not registered to do business in the State of New York, and also for the reason that its contracts were against public policy.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy for week ending July 27, 1901: July 19.—Asst. Surgeon E. O. Huntington, detached from the *Newark*, when placed out of commission, and ordered home to wait orders. July 20.—Surgeon C. F. Stokes, ordered to the *Oregon*, immediately. Surgeon P. Leach, detached from the *Oregon*, upon reporting of relief, and ordered home to wait orders. P. A. Surgeon A. Frenholt, detached from the *Oregon*, and ordered home to wait orders. July 24.—Surgeon G. T. Smith, detached from the *Mayflower*, when put out of commission, and ordered home to wait orders. P. A. Surgeon D. N. Carpenter, detached from the Naval Hospital, Chelsea, Mass., and ordered to the *Franklin*. Asst. Surgeon R. R. Richardson, detached from the Naval Hospital, Newport, R. I., and ordered to the Naval Hospital, Chelsea, Mass. Asst. Surgeon J. R. Whiting, resignation accepted to take effect from August 3, 1901.

Obituary Notes.—Dr. Adolph W. Dunbar, of Brooklyn, died on July 20, of typhoid fever, at the age of twenty-eight years. He was a graduate of the Bellevue Hospital Medical College in 1896.

Dr. Michael A. Arnhalt, of Pittsburg, killed himself on July 25. He was graduated in medicine, in 1860, from a Cincinnati college, but had passed nearly all his professional life in Pittsburg. He was at one time a member of the Pennsylvania Legislature. He had been in poor health for two years.

Dr. Frank K. Paddock, of Pittsfield, Mass., died in that city on July 26, of disease of the heart, from which he had long been a sufferer. He was medical examiner for Berkshire County, and it is thought that his death was accelerated by the fatigue incident to a recent murder trial, in which he was an important witness. He was a graduate of the Berkshire Medical College in 1864. He was a member of the Massachusetts State Medical Society and of the American Medical Association.

Dr. Joshua Miller, of Prescott, Ariz., one of the foremost anthropological students of this country, died recently at Flagstaff, Ariz., of pneumonia, after a brief illness. He was born in Missouri fifty-five years ago, and was graduated in medicine at the University of Michigan, in 1872. Dr. Miller spent nearly a lifetime in the study of prehistoric races in the southwest, and had almost completed his researches, which he believed would establish the fact of a connection between the Pueblo Indians and the earliest inhabitants of this continent.

Dr. Leonidas Russell, a medical examiner in the Pension Office, died at his home in Washington, on July 26, at the age of sixty-six years. He was born in Indiana, and was graduated from the Jefferson Medical College, Philadelphia. He was practicing at Owensboro, Ky., when the Civil War broke out. He served as assistant surgeon to the Second Kentucky Volunteers, and was severely wounded in the battle of Shiloh. He was afterward a member of the Tennessee Legislature and received his appointment in the Pension Office in 1885.

Dr. William R. Argyle Watson died at his home in Newport, on July 27, at the age of seventy-four years. He was born in South Kingston, R. I., where his father, Dr. Daniel Watson, was the leading practitioner, and obtained his medical degree from the University of Pennsylvania. At the outbreak of the Civil War, Dr. Watson entered the navy as a surgeon and rendered valuable services in the Gulf of Mexico. After the war he practiced in New York.

Dr. Charles W. Hayt, of Corning, N. Y., disappeared from a steamer in Lake Erie, between Buffalo and Cleveland, during the night of July 23-24. It is believed that he fell overboard and was drowned, but his body has not been recovered. He was a graduate of the College of Physicians and Surgeons, New York, in 1889. He was a member of the Steuben County Medical Society and of the Corning Academy of Medicine.

Progress of Medical Science.

New York Medical Journal, July 27, 1901.

The Ophthalmoscopic Examination for Kidney Disease.—Edward Jackson, after a description of the method of examination, notes that swelling and opacity of the retina are usually confined to isolated patches, or to the region surrounding the optic nerve. The color of the patch may vary from a dirty red to a snow-white, or a gray-blue. The swelling is to be measured by the retraction of its summit. Sometimes it looks like a small detachment of the retina. But actual detachment may also occur. White spots arise from fatty degeneration. These are regarded as most characteristic when arranged in rows radiating from the centre of the macula. Large spots are confined to this part of the fundus or to the neighborhood of the optic disk, but small ones may be scattered in all parts of the eye-ground. White streaks are occasionally seen along the arteries or may wholly replace them. The optic nerve is often reddened and opaque. It may even be swollen until it exactly resembles the choked disk of brain disease.

Some of the Conditions following the Bottini Operation for Prostatic Obstruction.—L. Bolton Bangs calls attention to a condition not referred to in text-books and which offers a serious impediment to after-treatment. The obstacle is in the membranous and prostatic urethra, and it consists of a firm and rigid contraction of both these portions of the deep urethra. The catheter may be introduced for a short distance beyond the bulbo-membranous junction, and then it will be suddenly and firmly clutched, even while the patient is still under ether narcosis. That it is not due to rapid swelling Bangs is convinced from the fact that the muscular clutching can be felt and that it will let up in a degree when the catheter is slightly withdrawn, but when an attempt is made to introduce the instrument still further a forcible contraction takes place instantly, which holds the catheter so firmly that some force is required to extract it. In order to overcome this difficulty Bangs uses a series of special catheters made of metal, after the pattern of the Trendelenburg searcher, with solid tips. The results following forty-two Bottini operations in the author's practice were as follows: Over sixty per cent. of the subjects had thrown away the catheter, about twenty per cent. had an increased amount of spontaneous urination, and twenty per cent. received little or no benefit. There were three deaths directly attributable to the operation. Two of these were from sepsis, and the other was from shock.

Mental Disturbance in the Course of Cardiac Disease.—A. Zederbaum says that these abnormal mental conditions are easily referable to disturbed circulation through the brain. The character of mental disturbances in cardiac disease will largely depend on the altered circulatory relations inaugurated between the heart and brain by the specific pathological condition of the former. Thus in mitral incompetency, when there is an obstruction to the recurrent flow of the blood we would expect venous engorgement and passive hyperæmia. When the aortic orifice is narrowed, we expect cerebral anæmia, and the mental states from these two respective conditions will vary accordingly. In valvular insufficiency of the mitral, mental depression, gradually developing into simple and agitated melancholia, is the predominant form of psychosis. The patient appears reticent, downhearted, apathetic, and dissatisfied with both himself and his surroundings. Instances of suicide are not infrequent in this condition, decidedly more so than in affections of the aortic valves. Altogether, psychoses are more frequently observed in connection with aortic defects than in failure of the mitral. The symptoms of mental disturbance here partake more of the nature of mania, and resemble the delirium of alcoholic pneumonia. Extreme irritability, excitement, fretfulness, restlessness, inconsistency, and querulousness, make it sometimes very difficult to control the patient. The contrast between his usual ways of acting and thinking and the observed change in temper, not infrequently amounting to violence, is so striking that suspicions of insanity even enter the mind of those who take care of him. These suspicions are often too well-founded, and become confirmed in the outbreak of a real mania with all the distressing features and consequences of this special form of psychosis. Troublesome and exhaustive sleeplessness is especially noticeable in aortic insufficiency.

Medical News, July 27, 1901.

A Nasal Condition Affecting the Ocular Muscles.—Heber Nelson Hoople concludes from his studies that a moderate amount of pressure on, or mechanical irritation of the middle turbinate and adjacent septum, will temporarily impair the function of the ciliary muscle, and to a less or more variable extent or will also impair that of the external ocular muscles. The effect of severe continuous pressure, like that from a spur or a bend in the septum, when it digs into a broad surfaced middle turbinate, will naturally be much more severe.

A Case of Embolism of One of the Right Lenticulo-Optic Arteries Complicating Pneumonia, with Autopsy.—Charles J. Aldrich reports the case of a boy aged eleven years, who was suffering from an attack of pneumonia. On the ninth day of his illness, he began to have general, jerky, choreic movements which continued without intermission for over twenty-four hours, at the end of which time it was noticed that he no longer moved the left arm or leg, the face, however, was not drawn to one side. The pupils were wide throughout his illness. There was no skin eruption and no complaint of stiff neck, nor was there any rigidity of the neck or spine. The head was turned toward the right with a conjugate deviation of the eyes toward the same side—away from the paralyzed side. The patient died from heart exhaustion following acute dilatation. On examination, the brain and membranes seemed normal, only that the vessels were slightly injected. An area of softening was found in the region of the posterior half of the right lenticular nucleus, and the hinder part of the posterior limb of the internal capsule, slightly involving the optic thalamus. There was complete embolism of one of the middle lenticulo-optic arteries. The other cerebral vessels seemed to be normal and there were no other areas of softening found. No embolism was found in spleen or liver.

An Improved Method of Treating High-seated Cancers of the Rectum.—Robert F. Weir describes this method as follows: With the fingers he freely detaches the divided peritoneum so that the bowel and the entire contents of the sacral curve are liberated behind nearly to the tip of the coccyx and in front to the edge of the prostate. This gives room to tie around the bowel, some three inches from the anus, a couple of iodoform tapes about one inch apart. The intestine is then cut through and, being free, is readily raised out of the abdominal wound and held aside by an assistant. The lower end of the rectum is seized by forceps in the hand of an assistant who draws it down and out of the anus in an everted condition. By untying the tape that closes the everted bowel its lumen is opened so that a long forceps may be carried through it up into the pelvis; then the end of the upper bowel is brought down within its clasp and by it the latter is drawn through the lower bowel out into the world. The passage of a couple of needles through the invaginated ends of the bowels, near their margins, allows easy union by suture of their edges with their knots inside the bowel; replacement of the latter is then effected. After the peritoneum is sewn together and to the bowel so that the pelvis and general abdominal cavity are separated from one another by the peritoneal shelf, the writer provides drainage from the peri-intestinal space below by a tube introduced from just in front of the coccyx. The results of this operation have been very gratifying.

Journal of the American Medical Association, July 27, 1901.

Unusual Anomaly of the Faucial Tonsil.—G. L. Richards says that in a woman of sixty years, who had complained for a long time of pain in the general region of the tonsils and extending to the ears, the tonsils were found to be enlarged. Attempted removal with the tonsillotome was found to be impossible and examination revealed a bony mass on the right side running into the tonsil and almost through to its outer border. This was removed with bone forceps and found to be a portion of the styloid process. A similar condition was found on the left side, though to a less degree.

Anomalies of the Frontal Sinus and their Bearing upon Chronic Suppurative Sinusitis.—R. W. Payne, commenting on the anatomical difficulties in working on the region named, says that his favorite operation is to make successive openings through the anterior wall, exposing every part of the sinus, but leaving bridges of bone to support the skin. He also leaves an opening at each angle of the wound, the external opening being at the limit of the external angle of the sinus. This allows for free irrigation. If the disease is of long standing and the cavity is large, permanent drainage is secured by making a large opening into the nose along the line of the infundibulum, and the recesses of the cavity are wiped over with a twenty-per-cent. solution of zinc chloride. In five or six days the external wounds are closed, the edges being freshened and brought together, a trifling scar only being left.

The Effect which the so-called Catarrhal Diseases of the Nose and Throat may have upon the General Health.—Carolus M. Cobb says that diseases of the nose and throat affect the general health through obstructed nasal respiration, or by extension of the diseases of bacterial origin. The diseases of bacterial origin affect the general health: *a*, by extension upon the surface membrane; *b* by the migration of bacteria to surrounding tissues or to distant parts of the body; *c*, by swallowing of the discharge; *d*, by the absorption of toxins. The migration of bacteria takes place through the lymph current or through the blood. Septic infection originating from disease of the nose and throat does not differ materially from infections from other sources. Much of the indigestion from which these patients suffer is caused or made worse by the swallowing of the secretion, and finally a condition of chronic sepsis may be caused by a purulent collection in the nasal chambers or accessory sinuses.

American Medicine, July 27, 1901.

Lithæmic or Recurrent Coryza.—B. K. Rachford states that an attack of lithæmic coryza is sudden in its onset, and is characterized by intense photophobia and hypersecretion from the eyes and nose. The profuse watery discharge from the nose irritates and causes redness and swelling of the lip over which it flows, and the eyes are also red and swollen. The patient is extremely nervous and irritable, and there is generally some elevation of temperature. These symptoms last for two or three days and then disappear as rapidly as they come. Within a few days the patient is quite well and may continue so for a variable length of time, when, without apparent exciting cause, a similar attack recurs. There seems to be every reason, clinically, to believe that these cases are produced by lithæmic poisons acting, as they usually do act, through the vasomotor nerves. The writer believes that lithæmic coryza is not an uncommon symptom group.

Inflammation of the Sigmoid and Colon.—R. D. Mason believes that diagnosis of the various inflammatory conditions of the large intestine is difficult because little can be determined by physical examination, and subjective symptoms must mainly be relied upon to arrive at correct conclusions. The chief symptoms of inflammation of the sigmoid and colon are diarrhœa and abdominal pain, although the latter is often not prominent, except in acute cases. Diarrhœa, however, is always present. In obscure cases, the sigmoid should be explored and treated. The writer mentions colostomy for the cure of amœbic dysentery and other inflammatory conditions. It has been so seldom tried, that its value has not been fully demonstrated. He believes that it will save many lives. He speaks of the value of high injections, emphasizing the importance of slowly filling the colon first, allowing the rectal pouch to be filled last so that desire for evacuation will be presented.

Philadephia Medical Journal, July 27, 1901.

Report of Cases Examined for the National Jewish Hospital for Consumptives at Denver, Colorado.—Saling Simon finds that out of the two hundred and four patients admitted to the hospital, one hundred and twenty-five were improved, thirty-nine were unimproved, seventeen became worse, and twenty-three died. A prominent feature was the predominance of involvement of the right lung over that of the left. A cold contracted in exposure necessitated by their work was assigned as the direct cause by eighty-three patients. The occupations were exceedingly varied. The largest number of patients had been employed as tailors, most of them in the sweat-shops of New York and Chicago. The influence of indoor work and bad hygiene seemed clearly shown. The family history in one hundred and fifty-two cases was negative. A rapid pulse, even without fever, seemed to be almost the universal rule. In the treatment, climate, nutritious food, and personal hygiene were mainly relied upon. As to medication, the patients were treated symptomatically. Fever was best combated by putting the patient to bed.

Treatment of Infantile Diarrhœa.—William H. Robey, Jr., gives the following treatment for this affection: Cleanse the bowel of bacteria and their toxic products. Give the remaining bacteria as unfavorable conditions as possible for further production. Soothe the irritated intestines when the continuance of the condition makes this necessary. Support the patient against constitutional symptoms, such as fever, nervous irritability, etc., as in other acute diseases of childhood. Guard against infection of others by isolation, when possible, and by carefully washing the hands after handling the stools in order not to infect the food and common household articles. The writer prefers calomel [illegible] purge. He believes in washing out the bowel, which [illegible] by passing a large soft rubber catheter into the [illegible] allowing the fecal salt solution to flow in during its passage, thus dilating the bowel and facilitating the introduction. At least two quarts of the solution are used, the bag of the syringe being held about three feet above the table. The washings are carefully strained. It is a good plan to tell mothers going into the country with their children to stop food for twenty-four hours at the very onset of a diarrhœa. When there is vomiting, the stomach as well as the bowel should be washed out. When feeding is resumed, a weak sterilized milk is used. When irritability of the bowel continues bismuth is administered. Opium is used only when pain is a marked symptom, and when the stools are frequent.

The Boston Medical and Surgical Journal, July 25, 1901.

Adhesive Plaster Strapping in Umbilical Hernia.—J. C. Hubbard says that an umbilical hernia is ordinarily cured by adhesive plaster strapping. The younger the child, the earlier the cure is to be expected. The danger of recurrence or failure is slight. The author reports twenty-eight cures out of sixty-six cases.

Diphtheria as a Complication of Measles.—David Newton Blakely and Fred Grant Burrows suggest that the existence of diphtheria or the possibility of its onset should be considered in every case of measles, the congestion of the mucous membrane of the tonsils and air-passages caused by the measles process rendering it especially vulnerable to the growth of the diphtheria bacillus. Nasal or laryngeal obstruction arising during an attack of measles almost certainly means diphtheria; disappearance of the initial fever, or a sudden rise later, or a brassy and paroxysmal quality of cough, or persistence of initial fever and development of aphonia, all point to diphtheria. So does a purulent or muco-purulent discharge. In all obscure cases the patient should be given the benefit of the doubt—*and antitoxin.*

The After-Treatment of Operation on the Nasal Accessory Sinuses.—Walter A. Wells says that the after-treatment in these cases requires not merely antiseptic applications to the sinus, but the patient's general state of health must be investigated, and a careful supervision constantly maintained over the conditions of the nasal fossæ. The latter must be kept free from secretions, and polyps and other obstructing conditions removed whenever found. Frequent and thorough irrigations constitute the most rational method of treatment. Protargol, in two to five per cent. solution, has given the most favorable results, especially when alternated with a thorough swabbing of all parts of the inner wall of the sinus with a twenty to forty per cent. solution in water or glycerine. Immediately after the operation the sinus is packed with iodoform gauze, which is left in from thirty-six to forty-eight hours. Subsequently the sinus is irrigated daily, and later on every other day. The walls of the sinus should be rubbed with the solution mentioned every three, four, or five days as required.

The Lancet, July 20, 1901.

Malignant Disease of the Testicle in an Infant.—H. J. Clark reports the following rare case: The second child of exceptionally healthy parents was born in January, 1899. At birth, the testicles had descended, and no abnormal condition was observed until the child was ten weeks old, when a slight enlargement of the left testicle was observed, without, however, any apparent cause. The enlargement in the gland increased gradually until the child was eleven months old, when it had attained the size of a small hen's egg. There was an entire absence of swelling in the inguinal or neighboring glands. On removal the testicle weighed twenty-nine grammes. After operation the child did well and at present looks healthy and is free from any neighboring glandular implication.

Headache.—A. H. Copeman says that intracranial headaches may be classified as follows, the classification suggesting in each case the appropriate remedy: (1) Headache the result of gross lesions of the brain or of the vessels or membranes of the brain; (2) headache occurring at the onset of the acute fevers, especially that of typhoid fever; (3) congestive headache; (4) anæmic headache; (5) nervous headache; (6) toxæmic headache; (7) sympathetic or reflex headache; and (8) migraine or sick headache. Concerning the last-named variety the author is strongly inclined to place it in the toxæmic group and to refer the symptoms to profound poisoning of the substance of the brain by a blood loaded with the toxic products of incomplete and faulty digestion. But little can be done for the unfortunate sufferer after the incidence of the attack. The author is in the habit of prescribing a powder consisting of five grains of phen-

acetin with two grains of caffeine, but from twelve to twenty-four hours' rest and a night in bed will be necessary before complete relief will be secured.

Infantile Scurvy.—E. Cautley reports four cases, the first being due to a prolonged diet of sterilized cream and milk, the second and third to patent foods, and the fourth to sterilized milk. In the first case the milk mixture was given boiled instead of sterilized, and in addition the child was given barley water, fruit juice, and a little meat juice. Recovery was rapid and uneventful. The treatment in the other cases consisted in a diet of unboiled milk, fruit juice, meat juice, and barley water. In the fourth case vegetable purées were also given and mashed sieved potato. All these cases occurred in infants in well-to-do families, and they had all been more or less under medical supervision. Climate does not appear to have exerted any influence, though it is possible that the healthy hygienic surroundings and a copious supply of pure air may have postponed the onset of the disease. In all cases the diet consisted of a cooked food, but the disease did not develop for many months. The first case was the mildest, although the food had been continuously sterilized for eight months and it was not necessary to stop cooking the milk in order to cure the disease. The milk was boiled for a few minutes instead of for twenty minutes.

The Deciduous Dentition as a Factor in the Health of the Child.—W. H. Dolamore lays stress on the importance of caring for the first teeth. They should be cleaned thoroughly twice a day, and this habit cannot be begun too early. If an infant has only one tooth that tooth will be all the better for the cleansing. They should also be periodically inspected and small holes, when present, should be filled. He assumes that the teeth are cut in an approximately perfect state. During the earlier stages of caries of the teeth the constitutional effects are slight, and perhaps transitory; though in a delicate child the pain on attempts at mastication may lead to a refusal to take any but the softest food, and this might possibly not be without its permanent effect. But caries is, almost without exception, progressive—not only leading to exposure of the pulp in a particular tooth, but spreading to other teeth, including those of the permanent series, owing to the acids formed by the decomposition of the food which collects in the cavities of decay. Moreover, although the vessels of the pulps of the temporary teeth do not become so quickly plugged, owing to the larger size of the apical foramina, as they do in permanent teeth, yet the septic inflammation, which must necessarily ensue when the pulp is exposed, will inevitably in time cause their death. The septic condition of the mouth now becomes worse, for to the previous factors there are added the breaking up of the gangrenous pulps and the collection of food in the pulp-canals, where it remains free to decompose, unreached by the tongue or the ordinary cleansing processes, whether of the brush or the mastication of food or the drinking of fluid. Moreover, either by the direct spread of the inflammation or by the forcing of virulent septic organisms through the apical foramen by the piston action of a plug of food forced into the tooth cavity, acute inflammation in the surrounding tissues may directly follow. But even supposing this may fortunately not happen, the periosteum of such a tooth is almost always chronically inflamed, as is frequently seen when it is removed. Certainly, so long as the pulp is not exposed, probably so long as an exposure does not lead to any extensive disease of it, no germs or germ products will be absorbed into the blood stream; but when the pulp is dead this inevitably happens to a greater or less degree.

The Pathology of Hysteria.—T. D. Savill says that hysterical attacks differ from all other kinds of seizure in one very remarkable way, viz., that they can be produced in a large number of instances at will by pressing firmly and steadily on some part of the patient's body, usually the inguinal region. Pressure on the inguinal region on either side produces either a complete syncopal attack or the same disagreeable sensations which form its initial stage, and which are collectively known as the "aura." This sensation then rapidly rises up from the groin and the abdomen towards the chest and throat and terminates in the feeling as of a ball in the throat (globus hystericus). Sometimes the bystanders can hear the patient make a gurgling attempt to swallow "the ball." In other subjects pressure in this region produces sighing and a feeling of "faintness and sinking in the abdomen." The series of sensations so produced is generally called in England 'ovarian tenderness," but nothing could be more misleading. It has not the slightest resemblance to the tenderness felt when pressure is exerted in this region. It is best to call it as the French do, the "ovary," or better, perhaps, the "inguinal or hysterogenic phenomenon," for it may exist in a very complete form in hysterical males. It only exists when the patient is or has been, the subject of some form of hysterical attack. It may thus terminate in rigidity of the limbs, or tremor, catalepsy, or convulsions, local or general. The points, pressure upon which will produce the sensations just described, are called in France "hysterogenic zones," and though the inguinal region is the most frequent, the subinammary region is another situation, and altogether there may be, in some cases, a score of hysterogenic zones, in different parts of the trunk; never on the limbs. In some patients, in whom a number of such zones exist, pressure upon one of them will produce an attack, while pressure upon another point, or a second pressure upon the same point, will stop it. If these phenomena have anything to do with the ovary, it is curious that they should occur in the male, as they do, in a very marked manner. Nor are they connected with the testicle apparently, for in male hysterical subjects this organ is only very occasionally the seat of "ovarian tenderness," and then it is undescended. By far the commonest position of the hysterogenic zone in male patients is the inguinal region, the region which is supplied by the ilio-hypogastric (and sometimes, less or more in different subjects, by the ilio-inguinal) nerve. This nerve is centripetal. It starts from the skin over the buttock and the inguinal region, and passing into the abdominal cavity it joins the first lumbar nerve-trunk, where it comes into very intimate relation with the solar plexus, the largest mass of sympathetic ganglia and fibres, not only in the abdomen, but in the body. There are good reasons for believing that such attacks are due to the sudden dilatation of the abdominal vessels, and, if this line of reasoning is correct, we can understand how it is that pressure in the inguinal region may produce the aura and all the succeeding phenomena of an attack. The ilio-hypogastric nerve is apparently the centripetal depressor nerve of the abdominal sympathetic, and irritation of it by pressure in this region produces dilatation of the splanchnic area and consequently cerebral anæmia. There may, apparently, be other depressor nerves in patients who present other hysterogenic zones.

British Medical Journal, July 20, 1901.

The Treatment of Whooping Cough by Irrigation of the Nares.—Walter Lattey believes this method is worth a more extended trial. The child should be rolled in a shawl to confine the arms and laid face downward. A soft india-rubber tube is as good as anything. Tepid water should be slowly passed through the nostril and be followed by an antiseptic solution. Both sides should be treated.

Case of Snake Bite.—J. Ronaldson Russell reports the case of a boy, aged fourteen. He was bitten by a common adder on the thumb. In a few hours he was in a state of collapse, sweating profusely, vomiting bilious fluid, and suffering great pain. He was given a hypodermic injection of strychnine and morphine, and meat juice with soda water was given internally. Hot fomentations were applied to the arm and hand. Later, the swelling extended over the chest into the neck. The blebs were punctured and very hot arm baths of an antiseptic solution were ordered every hour, the forearm being enveloped in antiseptic wool in the intervals. A saline laxative was also given. In a week the boy could use his hand. There was no suppuration.

Œdematous and Erysipelatous Anthrax.—John Henry Bell states that this affection has received its name from its resemblance to erysipelas, not that it is a compound of the two diseases. The virus may pass through natural openings of the skin or mucous membrane. The general symptoms are of a negative character. The freedom from pain and distress are remarkable. The striking local symptom is the extensive œdema, which may extend from the scalp to the pubes. The only proof of the existence of the disease is the finding of the bacillus by cultures or physiological tests with blood or serum taken from the body. This form of the disease is far more dangerous than the pustule. Probably the most promising method of treatment is the intravenous injection of non-toxic germicides.

The Danger of Anthrax from the Manipulation of Horsehair, and its Prevention. Alexander Scott, after pointing out the danger from working in horsehair, suggests the following precautions for the prevention of anthrax: All workers should wear overalls. No one with any cut, sore, or abrasion of the skin should be allowed to work unless it can be absolutely protected from contamination. All workers should wash themselves frequently, and especially before taking food. All illnesses, especially if connected with any swelling or boil, should be at once reported to the manager. The bales

should be immediately immersed in water and raw material handled only in the wet state, for this microbe may be carried in the air. The hair should be boiled for thirty minutes, after which steam should be applied at a pressure of 0.15 atmospheres. Or boiling may be accomplished in a two-per-cent. solution of potassium permanganate, after which a three-per-cent. solution of sulphurous acid may be used for bleaching. All dust and residue must be carefully burned.

Munchener Medicinische Wochenschrift, July 2, 1901.

Removal of Fishbones from the Throat.—Max Breitung reports the case of a man who came to him for relief on the third day after having swallowed a fishbone which had lodged somewhere in the throat. Inspection with and without the laryngoscope showed no trace of the foreign body. Resort was then made to palpation of all accessible parts with the index finger, and a sharp point was detected on the surface of the right tonsil. Inspection thus guided revealed a white speck scarcely distinguishable from a drop of mucus, and by means of a forceps the offending bone was removed. The author argues from this experience regarding the necessity of palpation as well as inspection in any case in which a foreign body has lodged in the throat. The sensation of the patient is not to be relied upon, except as indicating the side where the body has stuck, for he almost invariably locates it too low down, referring the sensation usually to the level of, or even below, the larynx, when in reality the body may be imbedded in the tonsil.

The Albumin-Sparing Property of Alcohol.—R. O. Neumann says that, the results of some previous experiments having been called in question, he was led to submit himself to a careful and extensive test. His first experiment was as follows: After an abstinence of seventy days from alcohol, on a simple diet of bread, cheese, fat pork, and brain-sausage, he was in a state of nitrogenous equilibrium. Then he omitted half the quantity of fat from his diet, upon which there was an increased excretion of nitrogen. Now the missing fat was replaced by alcohol and after a short period, during which the system accustomed itself to the alcohol, the nitrogenous equilibrium was restored. When, with a full diet, alcohol was taken, its albumin-saving effect was shown by a further reduction in nitrogen elimination. In the fifth period the alcohol and part of the fat were cut off, and the excretion of nitrogen rose, but the equilibrium was restored again upon a return to a sufficient diet. The results of this experiment having been impugned the author submitted himself to a second one, in which the addition of alcohol to the diet was very gradual. The results were the same, demonstrating that alcohol is a true food, although not capable of taking the place of fat in every respect. But though a food in its action, it cannot be recommended for use as such, for it is in addition a poison when taken in quantities of 40 gm. and over. The author's conclusions are supported also by Clopatt in some personal experiments reported in the *Skandinavisches Archiv fur Physiologie*, Nos. 5 and 6, 1901. Neumann asserts therefore that there can be absolutely no question as to the nutritive action of alcohol.

French Journals.

Experimental Tuberculous Meningitis and its Treatment by Zomotherapy.—Ch. Richet and Jean C. Roux have studied the effects of cooked and uncooked meat in experimental tuberculous meningitis. They experimented on twenty dogs. All were inoculated aseptically by means of a Pravaz needle which was used to puncture the occipito-atloidian membrane through the skin and muscles of the neck. A constant phenomenon noted was the progressive hypothermia which the animals presented during the entire duration of the malady up to the moment of death. Of eleven dogs treated with the uncooked meat, three survived; of nine dogs treated with the cooked meat, one alone survived; but it succumbed to an injection of tuberculin, while the animals which survived after the treatment with the uncooked meat, resisted an injection of tuberculin.—*La Presse Médicale*, June 26, 1901.

Treatment of Intestinal Occlusion.—Gabriel Maurange states that the diagnosis of chronic occlusion is generally grave. This condition can be caused by constipation. In order to combat this condition, the various well-known means may be used. The various treatments, hygienic, dietetic, and medicinal, should be tried. Women and the aged will fall particularly into this class of patients. When the occlusion is caused alone by a collection of feces, purgatives are in order. Castor oil gives the best results, and is well followed in two hours by generous injections of oil or glycerine. Saline and drastic purgatives are generally contraindicated. Injections of boiled water with the addition of a little sea salt are also recommended. The use of the continuous current has given remarkable results. Massage of the abdomen is frequently successful. However, the cause of constipation lies frequently in the organic alteration of the intestinal walls. In such cases an early diagnosis is important. The contraction may be syphilitic or cancerous. In the first case, specific treatment should be instituted; in the second, according to the case, colotomy or enterectomy should be practised.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 23, 1901.

Tuberculosis of the Entire Suprarenal Capsules without Addison's Disease.—Ch. Le Roy reports this case. The patient was a man thirty-nine years old. He had always been in fairly good health till September, 1900, he developed an anal fistula; later he began to suffer from headache, which was followed by convulsive movements of the arms and legs. Vomiting apparently cerebral, supervened. There was incontinence of urine and feces. There was no fever, the pulse being between 90 and 100. Kernig's sign appeared. He seemed to be suffering from incipient facial paralysis of the left side. In less than three months from the development of the anal fistula, he died. Autopsy discovered an old pleurisy and total adhesion of the right pleura, but no or very few tubercles in the right lung. There were several caseous nodules in the left lung. There was old tuberculous ulceration of the small intestine. The kidneys were smooth and slightly congested. The suprarenal capsules were large, hard, and of unequal consistence. On section, large caseous masses had entirely replaced the normal substance. There was acute congestion of the meninges. The ventricles were distended with liquid. There were inflammatory areas at the level of the apparent origin of the cranial nerves. In a word, this case presents an old pleuro-pulmonary tuberculosis predominating on the right side, tuberculosis of the intestine and the suprarenal capsules; finally, tuberculous meningitis. The symptoms of Addison's disease were wanting.—*Journal des Sciences Médicales de Lille*, June 1, 1901.

Meditsinskoe Obozrenie, June, 1901.

A New Symptom of Local Asphyxia of the Extremities, or Raynaud's Disease.—A. I. Pospieloff showed several years ago that biting the nails is not merely a bad habit, but a symptom of Raynaud's disease. Among the so-called bad habits there are some which depend upon physiological processes and accompany the normal development of the organism, and others which are the expressions of pathological changes in the body. Thus, for example, *perlèche* is the result of repeated moistening of the corners of the mouth with the tongue. Intelligent persons who are addicted to the habit of biting their nails state that they are impelled to do this, especially when they are excited, by a feeling of weight and fulness at the finger-tips. Some medical students are addicted to this habit only when studying before examinations, and when these have been passed, they let their nails grow in the normal way. In some persons the habit begins in infancy and continues throughout life. The author reports the case of a woman aged thirty years who came to him with trophoneurotic alopecia areata and Raynaud's disease. She had ten children and all of these since infancy had bitten their nails. The father was sixty-four years old and since childhood had bitten his nails, while the same habit was present in the mother and in two of her aunts on the paternal side. The author thinks that this symptom is a result of the peculiar venous stasis in the ends of the fingers in these patients, and the gnawing of the nails is but a way of relieving the numb, heavy feeling in the finger-tips. Nail-biting is therefore a neurosis of the skin, comparable to Hallopeau's trichotillomania.

Syphilitic Lesions of the Heart and their Treatment.—S. I. Schwartz reports the case of a man aged thirty-seven years who had the symptoms and physical signs of mitral stenosis and who gave a history of syphilitic infection fifteen years previously. Iodides were used with success as regards the amelioration of the subjective symptoms. A year later, the heart symptoms became worse, and there appeared a swelling of the left wrist and of the left elbow with pain and a copper coloration of the skin over the affected regions. All these symptoms disappeared under mixed treatment. The author believes that the valvular lesion was due to the presence of a gummatous growth on the endocardium. Early and persistent treatment with the specific remedies will produce good results in these cases, but such treatment is of less value in the parasyphilitic lesions, *e.g.* aneurisms and heart affections with tabes. At the end of the treatment the patient's heart gave almost normal sounds when he stood upright, and it is possible that complete cures may be effected in such cases.

The Treatment of Extrauterine Pregnancy.—V. P. Fiodoroff reports twenty-seven cases of extrauterine pregnancy in which he performed operations within the past three years. In these colpotomy was performed in two instances, total vaginal extirpation in two, and laparotomy in twenty-two. In all these pregnancies the gestation was tubal, the right side being involved in sixteen cases, the left in eleven. The indications for the operation were in two instances suppurating hæmatocele, in the other twenty-five, either the presence of hæmatocele or hæmatosalpinx, or the onset of acute symptoms of rupture. The author prefers laparotomy to all other methods of reaching the seat of the trouble, and his results show in twenty-two laparotomies but one death, that occurring in a case in which there was a pyosalpinx.

The Practitioner, July, 1901.

The Notification of Phthisis Pulmonalis.—Arthur Newsholme believes that notification gives greater opportunities of preventing phthisis by enabling disinfection of infected rooms to be carried out, enabling the medical adviser to give instruction to the patient and relatives as to the exact precautions to be observed, and facilitating the removal of insanitary conditions of home and work which may have caused the disease or favored its development. He does not consider voluntary notification sufficient, though admitting it to be a step in the right direction, and thinks that this will be finally followed by some modified system of compulsory notification. One of his arguments in favor of some modified form of compulsory information as to all cases of phthisis is that the compulsion involved would remove the ethical difficulty experienced by some practitioners when it becomes necessary to inform the medical officer of health as to the illness of their patients.

Tuberculous Infection Through the Air Passages.—St. Clair Thomson gives statistics showing that the nose is least frequently attacked by tuberculous infection, the lungs most often, while the larynx is between the two in susceptibility. The reasons for the infrequent infection of the nose lie in its defensive mechanism: microbes in the inspired air current may be entrapped in the lining vibrissæ; others penetrating further are enveloped in a sticky mucus, hindering their development, while they are finally expelled by the action of the ciliated epithelium. Phagocytic action also comes into play. Primary tuberculosis of the nose is of extremely rare occurrence. Primary tuberculous infection of the larynx is very infrequent. Regarding the mode of access of the germ to the lungs, it is inconsistent with our knowledge of physiology and all the laws of probability to assume that it is possible for the germ to run the gauntlet of the intricacies of the upper air tract successfully and reach the lung and be lodged in its upper extremity. The author believes that infection occurs in most cases by absorption through the lymphoid tissue of the pharynx and nasopharynx. He thinks there is nothing to support the commonly accepted idea that the bacillus is inhaled directly into the pulmonary alveoli.

Tuberculosis in Childhood.—George F. Still states that the incidence of tuberculosis is not the same at all periods of childhood, but that there is a more marked susceptibility during the first five years of life, particularly the second year. This age incidence bears a relation to the mode of infection, which should be determined in order that prophylaxis may be successful. Statistics show the theory of milk infection to be untenable. The commonest mode of tuberculous infection in childhood and especially in infancy, is by inhalation, there being good reason to believe that the respiratory tract during the first five years of life is especially vulnerable; milk infection is next in importance. A third factor is the frequency of ear infection, the middle ear forming a primary focus, the bacillus passing up through the Eustachian tube from the nasopharynx. Measles and whooping-cough are two potent factors in the causation of tuberculosis in early childhood, many cases following immediately upon these diseases. Glandular affection is prominent in the tuberculosis of childhood. Lung affection in children is more acute and more diffuse than in the adult. In accordance with this tendency to generalization, the outlook in pulmonary tuberculosis at this age is very grave; there is, however, post-mortem evidence that a tuberculous lesion in the lung or mediastinal glands, even in very early life, may heal. The author does not consider tuberculous meningitis as primary. In view of the fact that the majority of cases of tuberculosis in early childhood are due to the breathing of infected air and not to the ingestion of infected milk, fresh air is the foremost prophylactic agent. Sterile milk is next in importance. Inasmuch as tuberculosis frequently follows measles and whooping-cough, the [illegible] diseases should be as carefully guarded against as are other specific fevers. Prophylaxis will accomplish more than treatment in the tuberculosis of childhood.

Zomotherapy in Phthisis.—Leonard Robinson gives a résumé of the treatment of phthisis by raw meat as based on the experiments of Richet and Hericourt; the latter considers that "raw meat or the plasma pressed from raw meat acts by the antitoxic agents therein contained, elements which effectively combat the tuberculous intoxication." These experimenters have not yet been able to decide whether the muscle plasma is an antitoxin, whether it stimulates phagocytosis, or whether it is solely a special tonic to the nervous system. The author suggests, in explanation of the action of the plasma, that the nerve-cell fixes the ptomains, leucomains, albumins, enzymes, and diastases of the muscle as they circulate in the blood. But the cell saturated with nutritive principles can no longer fix the tuberculin, and thus the evolution of the tuberculous disease can take place without danger to the individual; "the nerve cell has become refractory to the poison." The point of interest, however, to the physician is the fact that zomotherapy is not a method of hyper-alimentation, and also the fact that the success of zomotherapy depends on the maintenance of a minimum ratio between the weight of the patient and the quantity of muscle juice or raw meat ingested. Below the minimum limit the disease is ameliorated, but cure is not to be expected.

A Case of Lupus Vulgaris of Twelve Years' Standing Treated with Urea and Cured.—Arthur H. Buck presents the case of a man, thirty-six years old, whom he describes as possessing the tuberculous diathesis to the last degree. At the beginning of treatment, the lesion consisted of a large ulcerated surface extending over the forehead, root of the nose, and both cheeks. The upper lip had almost disappeared, the left lower eyelid was absent, and all of the nose was destroyed except an irregular bridge of tissue between the two maxillæ; through a hole where the nasal bones had existed one could see the nasopharynx. The palate was perforated. The patient was of the poor class and his habits and diet were not such as would facilitate the cure of any tuberculous trouble. On March 26, pure urea (20 grains in 1 ounce of peppermint water, with maltine ½ ounce) was prescribed. The ulcers were dressed with iodide of lead ointment. Within a fortnight the discharge diminished, the granulations appeared more healthy, and the nodules began to subside. April 23, the dose of urea was increased to 30 grains, in a week to 40 grains, and a week later to 50 grains. On May 27, the ulcer had nearly healed, and the urea was increased to 1 drachm three times a day. At the date of the report all nodules had disappeared with the exception of a small area in the center of the forehead, and the ulcerated surface was entirely covered. No bad symptom of any kind occurred throughout the treatment. Other cases of tuberculosis are being treated with urea with gratifying results, and the author thinks that the discovery of urea as a remedy for tuberculosis will mark an epoch in the history of this disease.

A Personal Experience of "Galloping Consumption."—R. Mander Smyth reports his own case in detail. His family history was good and he had never had influenza. He was twenty-eight years old, and weighed 154 pounds. In March, 1896, the disease appeared suddenly while he was in the midst of apparent health. The development was rapid and the symptoms very acute with high temperature; within six weeks the patient was too weak to walk. He was living in a country house 400 feet above the sea level and kept his windows open all the time. For two months he lived on liquid diet, at the end of that time taking solid food. In July he went to Nordrach, in Baden. At this time there was a cavity at the lower border of the upper lobe of the right lung, and he had copious expectoration teeming with tubercle bacilli. A severe reaction followed the journey to Nordrach, appearing five days after his arrival. The treatment at this place embraced rest, absolute quiet, exclusion of all visitors, keeping all the windows (nearly covering one side of the room) open day and night regardless of weather and three daily meals. A sample meal is given: "A plate of pork and potatoes, a leg and wing of a chicken, salad and more potatoes, and a large wedge of very solid pastry." This the patient was encouraged to eat, the mental stimulus adding greatly to his ability to dispose of the food. In five weeks he had gained twenty-two pounds and his temperature had dropped to normal. He was kept in bed until the temperature had been normal for twelve days, when he was allowed to walk fifty yards. Exercise was gradually increased and he continued to improve. The bacilli disappeared by the end of October and in December he walked fourteen

miles over rough mountain ways. In January, 1897, a relapse from over-exertion necessitated five months more of treatment. In July of that year he returned to England, where he has since resided, weighing now 192 pounds. He considers the open-air rest-treatment at home to have failed on account of inadequate feeding, rest not being absolute, and insufficient ventilation of his room.

The Scottish Medical and Surgical Journal, July, 1901.

A Case of Acute Fatty Degeneration of the Liver.—Arthur H. Lister reports a fatal case in a child of six years. The illness lasted only twelve days and was characterized by vomiting and drowsiness at the outset and later by jaundice, slight albuminuria, slight pain, fits, hemorrhages, and coma. At the autopsy, the liver was found to be enlarged and in an advanced state of fatty degeneration. Small hemorrhages were found in the mediastinal fat, the parietal peritoneum, the omentum and mesentery, the mucous membrane of the stomach and of the middle and lower part of the ileum. The history of the illness and the results found post mortem point to some powerful poison taken in by the alimentary canal and absorbed by the portal system, or to acute yellow atrophy (except that the liver did not shrink.)

Alopecia Areata—Norman Walker and Marion B. Marshall-Rockwell give statistics of sixty-three cases of this affection occurring in Edinburgh. Their investigations were made with a view to ascertain the etiology of the disease. Ringworm would appear not to have had any causative connection, nor did their observations tend to uphold the theory that the disease is due to some nerve disorder. On the other hand, Saborand's theory that the disease is due to a fine bacillus, identical with that which is found in seborrhœa and in acne vulgaris, was supported by the fact that organisms were found in hairs taken from every case. Seborrhœa was found in a large proportion of the cases. Saborand holds that the organism produces a toxin which stimulates the oily secretion of the glands and leads, as does seborrhœa to the gradual death of the hair. He regards alopecia as an acute circumscribed form of seborrhœa.

Note on a Case of Perforating Gastric Ulcer Ending Fatally on the Eighth Day after Operation.—A. A. Scot Skirving reports this case of a young woman who had suffered from symptoms pointing to ulceration of the stomach for over eighteen months. A severe attack called for immediate relief, and laparotomy was performed. After a careful search, an air bubble appearing under a fold in the posterior wall of the stomach disclosed the rupture, which was so small that only a No. 3 catheter could be introduced. The site of the ulcer was one and a half inches below the middle of the lower curvature. Closure was effected by invagination of the stomach wall by a double row of Lembert sutures. Extravasation was so slight and the long operation was being so badly borne by the patient that only the upper part of the abdomen was flushed out. Death occurred of peritonitis on the eighth day and the conditions found post mortem would seem to indicate that rigorous flushing out of every recess, with a drain placed in the pouch of Douglas, should have been done.

OUR LONDON LETTER.

(From Our Special Correspondent.)

WEATHER—HEAT WAVES—ARMY MEDICAL SERVICE INQUIRY—LONDON WATER BILL PROMISED—SCHOOL BOARD REJECTION OF MEDICAL CERTIFICATES—DESTRUCTION OF BIRDS AND ANIMALS—SHOULD MILK BE BOILED?

LONDON, July 12, 1901.

EACH time we have read in our papers of your distress under a heat-wave some of our professedly weather-wise people have assured us that wave would surely come our way. Early in the week we were enjoying comfortably cool weather, and laughing at those who predicted without knowing. The tune has changed now. Whether it comes from you or not, we are having something of a heat-wave, and while the sun is up we are too languid to carry on a discussion as to whence it comes. Yesterday was our hottest day this year, 87° F. in the shade. This was exceeded in some places, 90° and above being reached. In one railway station under glass 100° was registered. In the country, especially by the sea, the temperatures reported were much lower, *e. g.* at Brighton the highest was 68°; Margate, 69°; Ramsgate and Hastings, 71°. In the evening in London there was a considerable fall, and driving out afforded a delightful change. During the day, a number of casualties occurred; at most of the hospitals cases of heat-stroke and syncope were brought in, and fatalities are reported from other large towns. In manufacturing centers furnace men have been unable to continue their work, and many have gone to help farmers in the open air for a time.

Optimists are rejoicing that the War Minister's Committee of Experts" contains names of well-known surgeons, and anticipate that good results will soon follow. But history scarcely justifies too great expectations. For about half a century the real reforms required to make the medical service of the army popular have been urged on successive governments, and, whatever may have been the good intentions and even decisions of ministries, they have been frustrated by military jealousy. It took forty years to carry out some of the reforms recommended by the Herbert Commission, and others are still blocked. If the new committee will speak plainly as to this, it may be of service, but I notice some indications that are not favorable to such a course. I sent you the names of the committee; those of the civil surgeons who have been to South Africa during the war will be familiar to you, and their experience will be useful. They are men, too, who will not hesitate to express their views. To enforce them may be another matter. Professor Ogston spoke out freely two years ago on the defects of the service, and he has been to South Africa since in a private capacity, so that his present views should deserve attention. Dr. Perry's experience as Medical Superintendent of Guy's Hospital should be of value to the committee. Colonel Keogh and Major James will represent the R. A. M. C., and Surgeon-General Hooper the I. M. S. But the influence of both civil and military surgeons is to be diluted by two members, to be nominated by the Commander-in-Chief. Further, much disappointment is felt at the absence of the name of some medical officer of the highest administrative rank, whose experience could not fail to be valuable. Remembering the obstinate obstruction of the War Office to every recommendation of previous committees and commissions, I cannot suppress some doubts as to the reforms that may result from this. It was only with the greatest difficulty that Lord Lansdowne carried out, in 1898, the recommendation of the commission of 1848 on army rank for the medical service. Forty years for a paltry concession that ought to have been granted in forty days! And other recommendations of that commission are still refused; for example, "study-leave," which is no doubt difficult to arrange for while the service is undermanned. But the remedy for that is increase of the number of officers, which could easily be effected if all grievances were redressed—not otherwise. The country is getting sick of the ways of the War Office and the obstruction of military incompetence. The starving of the medical service is a scandal the public is beginning to see through.

Mr. Long, President of the Local Government Board, in an after-dinner speech the other day (we seem to be in a fair way of being governed by dinners), made a statement on the London water question of considerable importance. He actually pledged the government to introduce a bill next session, and as his department would be responsible for such a measure, we may take it for granted that his colleagues have agreed to his views. What those views are we can only judge by his rather vague remarks. They show, however, that he is at one with the Cabinet in disfavoring the County Council. Further, he appealed to the residential districts around London, some of which are not within the limits of the county, to look at the matter from more than their own local point of view, and not to forget that they derived immense advantages from their proximity to the metropolis, nor to be too exigeant as to what they might consider their rights. He suggested an attitude of give and take as a fit one for all interested. It is to be hoped this does not foreshadow a measure of shreds and patches. If the government is afraid to trust the County Council, let it at least give London a measure worthy of the position of the metropolis.

Does a seat on the School Board interfere with the exercise of common sense? There have been many indications of such an influence. I do not refer to the manner in which many have, with the sanction of the Educational Department, extended their schools beyond their authority, necessitating an Act of Parliament to indemnify them, but to the manner in which they prosecute parents without due consideration of circumstances, and to the way in which they ignore medical certificates. In a recent case the parents were dragged before a magistrate for not sending a child to school, although the doctor who attended her certified that he had known her for twelve months, that she had been seriously ill, and although better, was unfit to attend school, on account of valvular disease of the heart. One would have supposed that this would be enough, but the Board's representative asked for an adjournment to allow the child to be examined by one of their own medical officers. The magistrate yielded, and so the parents were put to further inconvenience and expense. This is the way the School Board makes itself obnoxious and endangers the cause of education.

There is danger in our rural England that the man with

a gun, who calls himself a sportsman, will exterminate some of the most beautiful and innocent of the living creatures that adorn the country. Birds are the favorite mark, and some are rapidly becoming extinct, in spite of the partial protection that has been granted them. But it is not only birds—anything alive is made target of as soon as it comes within the range of the callous person whose delight is to "kill something." And yet these very people pretend to be so compassionate that they would forbid a physiologist to make a hypodermic injection into an animal. We have Lord Llangattock's authority for stating that the sportsman's object is to kill and his practice is to wound thousands of pheasants in pursuit of that "sport." The other day the newspapers reported the formation of a new club for the express purpose of killing the squirrels in the New Forest. But his lordship and other antivivisectionists make no objection. They only see cruelty when some good to humanity is the object of a rational experiment.

To boil or not to boil—that is the question this week in many a medical circle. For years we have been warned in terms of strenuous urgency to boil all our milk, with special disquisitions on the responsibility of not making sure that children under our care never tasted unboiled milk. A young practitioner a few years ago, talking with one of the staff of his hospital, was reproved in unusual terms because he confessed that he had not had boiled milk served for their tea. It was laid upon him as a duty to insist on his cook boiling all the milk as soon as it was delivered. Now that it has become a common belief with the public, as well as the profession, that unboiled milk is dangerous and boiled milk safe and wholesome, we are called upon to reconsider the conclusion. Nay, more than that—a counterblast against the growing practice of boiling milk is made. Dr. Clement Dukes, of Rugby, who is the medical officer of the great public school there, has opened a vigorous attack in the *Lancet*, on the boiling of milk, to which he attributes serious consequences, the principal one being that "the nutritive value is very largely diminished" thereby, and he further declares "this is true also of sterilized milk." Dr. Dukes is not alone in this opinion. Dr. V. Poore has expressed a somewhat similar one, and Dr. F. J. Smith, of the London Hospital, has hastened to throw his influence into the same scale, declaring that his out-patient clinic consists "to a very considerable extent of babies, and it is simply heartrending to see the numbers of such helpless creatures who are made peevish, fretful, and even seriously ill by the pernicious effects of boiled milk on their nutrition." Another supporter, Dr. F. P. Atkinson, says he has for years "denounced the boiling and sterilizing of milk," and suggests that if cows spread tubercle as much as some believe, the wonder is that any family escapes. He gives, too, a hit at the open-air treatment in the remark that cows have of late been fed on fresher and more natural food, and in the open. So much for what I venture to think the unpopular side of this question. The other side is sure of a spirited defense. The challenge has, in fact, been at once taken up by Dr. Variot, of Paris, who relates the plan which has been adopted in that city of distributing sterilized milk to infants, who are inspected once or twice a week, and instructing the mothers as to its use. He has had some 1,000 infants treated in this way during the last five years, with the best results. He has never seen a case of Barlow's disease, and rickets is rare in France, as also is infantile scurvy. The only accidents he has seen are anæmia and constipation, and these more common in winter than summer. It looks, therefore, as if the treatment prevented summer diarrhœa, as it might be expected to do in the light of recent researches. I believe that a similar experience to that of Paris has been obtained in Glasgow, though at present on a smaller scale. Sterilized milk has been for some time distributed there, and the reports hitherto have been most favorable, and similar results have been attained in some other localities. We are certain to hear a great deal more on this subject. The cry at present is for facts, and it looks as if the objectors to boiling are more free with opinions than facts.

OUR PARIS LETTER.

(From Our Special Correspondent.)

EPIDEMIC OF TETANUS—REPORT ON THE BUBONIC PLAGUE IN GLASGOW—AFTER-EFFECTS OF COCAINE INJECTIONS—NEW TREATMENT OF CARBUNCLES—ARTERIAL TENSION IN NEURASTHENIA—DIFFERENT VARIETIES OF HYPERTENSION (HUCHARD).

PARIS, July 19, 1901.

EPIDEMICS of tetanus are not often seen nowadays, but at a recent meeting of the Society of Surgery Dr Reynier, of the Lariboisière Hospital, described one that had taken place in his service. Three patients were affected in two different wards, and two of them died. The last patient, who recovered, was given large doses of chloral, as much as 20 grams (300 grains) being administered, and these had a distinct effect on the symptoms. Dr. Guénu remarked he did not see how such epidemics could take place in a surgical service when proper precautions are taken. The treatment by antitetanic serum did not seem to be looked upon with much favor by those who took part in the discussion that followed. Dr. Delbet, who is one of the best surgeons in Paris of the younger generation, said he remembered a case in which a relatively benign form was very much changed after an injection, and the patient died the next day. Dr Brun, a noted surgeon for children, spoke of a similar case in a child three years old, who died twenty-four hours after an antitetanic injection. On the other hand, Dr. Bazy said he always had administered these injections to patients who had open wounds resulting from street accidents. Since he had followed out this practice, he had only had two cases of tetanus, with patients who had not been injected. When treating cases of tetanus, he always gave large doses of chloral as well as the antitetanic serum.

Dr. Van Ermenghem, a Belgian physician, has published a report on the bubonic plague in Glasgow, which shows how quickly energetic measures may stop the spread of an epidemic. The infected quarter was inspected thoroughly, all the cases were removed to the Belvedere Hospital, the inhabitants of the houses where cases had taken place were removed, and the serum was injected into all persons who had been near a case of plague. The physicians of the Belvedere Hospital did not, however, fulfil the indications given by Calmette and Salimbeni, and inject 150 to 200 grams of serum. Only twenty cubic centimeters were injected at a time, and out of nine cases treated in this way five were cured. Seventy persons were immunized, and only two had slight forms of bubonic plague, eight and nine days after inoculation, so that it may be asked if they were not already infected.

At a meeting held by the Society of Biology on June 15 Dr. Ravaut and Dr. Aubourg described the changes they had found in the cephalorachidian liquid after cocaine injection. They repeated the puncture in a certain number of cases in which headache was present, and they noticed that when the latter symptom was severe, the flow of liquid was more intense. A histological examination was made, and they found that the proportion of multinuclear lymphocytes was in correlation with the turbid appearance of the liquid, and the intensity of the pathological symptoms noticed. If an examination was made later, it was found that the number of lymphocytes diminished day by day, which showed that there was no chronic inflammatory condition such as is seen in locomotor ataxia or general paralysis. The cause of the reaction which is thus produced can not be due to the water injected, though there is some isotonic difference between distilled water and the cephalorachidian liquid. It would seem to be due to the cocaine, the action of which would be similar to that of a toxin.

Dr. Thiriar, professor of clinical surgery at St. Peter's Hospital in Brussels, has been advocating a new treatment of boils and carbuncles by the use of oxygen. All that is needed is a receptacle containing oxygen at a pressure of 120 atmospheres, a rubber tube, and a Pravaz needle. The apparatus should be tried by placing the needle under water and regulating the quantity of oxygen that escapes; the needle is then inserted at the base of the boil, and a certain amount of oxygen allowed to pass through. The core of the boil should also be treated in a like manner. Four to six injections should be made into a carbuncle. If there is already sloughing of the cellular tissue, oxygen should be passed through it by inserting the needle into the orifices already formed. This treatment acts very quickly, the pain dying out rapidly and the œdema decreasing noticeably. In a few days cicatrization is complete.

Dr. de Fleury has recently made a report to the Academy of Medicine on the condition of arterial tension in neurasthenia. According to this author neurasthenic patients can be divided into two categories, those who present hypotension, and with whom rest and the usual treatment bring about the desired result, and others who show on examination that they are suffering from hypertension due to autointoxication, and who are affected with gout, alcoholism, diabetes, and kindred affections. In the latter case physical exercise, a lacto-vegetarian regimen, and diuretics are indicated. Professor Huchard spoke on this same subject of hypertension at the Society of Therapeutics, and described three varieties: hypertension in arteriosclerosis, which demands treatment by the usual regimen, massage, veratrum viride, trinitrine, nitrite of amyl; pulmonary hypertension, which is often due to mitral stenosis, and portal hypertension, which is best treated by a lacto-vegetarian diet and abdominal massage.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Fifteenth Annual Meeting, held at Niagara Falls, N. Y., June 11, 12, and 13, 1901.

ARTHUR J. GILLETTE, M.D., OF ST. PAUL, PRESIDENT.

First Day—Tuesday, June 11.

The meeting was held in the International Hotel, Niagara Falls.

President' Address—Injuries to the Spine from an Orthopedic Standpoint.—Dr. ARTHUR J. GILLETTE, of St. Paul, delivered this address. After referring to the unfortunate and erroneous use of the term "spinal concussion," he presented a photograph from a case to show that the ligaments may be ruptured without fracture. In the living subject it was impossible to differentiate between dislocation and fracture except in cases of fracture of the posterior segment. Cases were cited to show that fractures of the vertebræ, even of the anterior portion, may exist without any paralysis. Operation in these cases was by no means easy, either for the patient or the surgeon. Excellent results often followed rest on a rigid bed with a weight-and-pulley extension. Waterbeds and air-beds should be especially avoided in these cases; far better was it to secure the requisite immobilization of the spine, and so remove the cause of bed sores. From our present knowledge it seemed to the speaker an open question whether laminectomy was ever justifiable.

Fracture of the Cervical Vertebræ with Report of a Case, together with Apparatus used in Treatment.—Dr REGINALD H. SAYRE, of New York, read a paper with this title, reporting several cases.

The Treatment of Pott's Disease by Continuous Overextension of the Spine—Dr. ROYAL WHITMAN, of New York, read this paper. He said that pressure and friction were the most important of the factors contributing directly or indirectly to the advance of the destructive process; hence the actual separation of the diseased surfaces afforded the best chance for repair. If this could be accomplished in the recumbent posture only, recumbency would become an essential part of the successful treatment. He employed a modified stretcher or Bradford frame, and in practice had found it desirable to reduce the width of this frame so that the dimensions were one to five, instead of one to three, as in the original. He had also found it a distinct advantage to bend the frame in such a manner as to secure overextension of the spine and the obliteration of all of its curves, both normal and pathological. It was better also to have a supporting fabric made of a single piece of canvas. Additional support was secured by the use of strips of felt on either side of the spinous process. If the plaster jacket were used, the child should be placed upon the frame immediately after the application of the jacket. The object of the paper was to advance the proposition that horizontal fixation should be the routine treatment during the destructive stage of Pott's disease.

A Convenient Method of Applying Plaster Jackets.—Dr STEWART L. MCCURDY of Pittsburg, said that the Bradford frame had proved very unsatisfactory in his hands because of its yielding. In its stead he made use of two pieces of steel laid across two boxes. The latter could be obtained at any house, and when covered with soft material they afforded a perfectly satisfactory and thoroughly unyielding support.

Dr. H. AUGUSTUS WILSON, of Philadelphia, said that for some years he had made use of a similar arrangement but with the patient lying face down. This gave a very desirable degree of posterior leverage, with perfect access to the patient, and yielded results far superior to the method of suspension

Dr. R. H. SAYRE agreed with Dr. Whitman concerning the advantages of keeping the children horizontal, and had always preferred for this purpose the wire cuirass. He did not like the jackets made with the Goldthwait frame in the supine position.

Dr. A. M. PHELPS of New York, said that there was no need for employing the recumbent position if good plaster of Paris and the requisite skill were used in making the jacket. The wire cuirass was the best support of its kind though expensive.

Dr. V. P. GIBNEY, of New York, said that he had made much more satisfactory corsets with the patient recumbent. He had modified the kyphotone so as to do away with the patient's objection to the pulling out of the bars.

Dr. JOHN RIDLON, of Chicago, said that he did not see how the bars could be pulled out if Dr McCurdy's method were used; moreover the position did not allow of the fullest hyperextension.

Dr. B. E. MCKENZIE, of Toronto, said that he had used with great satisfaction a modification of the Goldthwait frame in which no rods were employed. Enough felt was placed under the kyphos to give the proper support.

Dr. JOEL E. GOLDTHWAIT, of Boston, said that the particular form of apparatus employed was of secondary importance, the chief point being to secure that position which would give the desired hyperextension, and if this were done the jacket could be fitted better than when the patient was suspended.

Dr. R. TUNSTALL TAYLOR, of Baltimore, said that easy access to the patient was secured with the upright kyphotone. His objection to the rods was that they gave a false impression of the straightness of the spine

Dr. McCurdy, in closing, said that it was his practice to cut down the plaster jackets, and hence it was easy to remove the bars. The boxes could be tilted in order to secure hyperextension

Traumatic Coxa Vara and Incomplete Fracture of the Femoral Neck.—Dr. NEWTON M. SHAFFER of New York, presented a boy who for the past year had suffered with this condition. When the patient was first seen by him, about the first of the present year, there was present the classical position of fracture of the neck of the femur; there was over an inch of shortening and any attempt at motion caused pain. An x-ray picture showed an incomplete fracture of the femoral neck. With a proper extension brace, the boy had done well, and the shortening had been reduced. This brace had an automatic snap at the knee and a traction arrangement at the upper portion. He expected to secure a useful limb in a good position

Dr. V. P. GIBNEY remarked that if it could be demonstrated that it was possible to control the outward rotation and the spasm by this method it would certainly be a valuable one.

Dr. WHITMAN was of the opinion that there was a separation of the epiphysis rather than an actual bending of the bone. No apparatus like that presented could effect a cure, although the symptoms might be relieved; a cuneiform or a linear osteotomy would be required.

Dr. A. M. PHELPS said he had found that when a linear osteotomy was done the muscles separated the fragments; hence he was accustomed to do a cuneiform osteotomy.

Dr. JOHN RIDLON, of Chicago, said that he had treated at least one case of undoubted coxa vara in this way, and on removing the apparatus after two years and a half the coxa vara had increased. All that such treatment accomplished was to relieve pain and disability and apparently lengthen the leg.

Clinical and Radiographic Analysis of Twenty-four Cases of Fracture of the Hip.—Dr. H. AUGUSTUS WILSON, of Philadelphia, presented a summary only of this paper. As far as could be ascertained, all of the cases had been treated by extension for periods varying from four to six weeks. The maximum shortening had been two and one-half inches, and had been observed in three cases. While

the abduction function was excessive in one case, the adduction was excessive in ten cases. The rotation phenomena were absent in four cases and greatly impaired in two. The flexion phenomena were absent in one, slightly limited in sixteen, and normal in six cases. Eight of the patients had never attempted to walk. In twenty-two the mental condition had been good. Crepitus had been elicited in only three cases, bony union had occurred in nine, partial bony union in two, and fibrous union in thirteen cases.

Dr. B. E. McKENZIE, of Toronto, said that Nelaton's line was totally unreliable. Dr. Wilson's final measurements would be vitiated by abduction or adduction. They should be taken from the tip of the trochanter or from the anterior superior spine.

Dr. Wilson explained how he had avoided this error, and remarked that the radiographs showed that this method was probably as accurate as any known.

An Operative Case of Intrascapular Fracture of the Hip.—Dr. THOMPSON, of Scranton, Pa., presented a specimen from a case of this nature. The patient, a man of sixty-two years, had been injured in a mine, and no diagnosis had been made up to the time that Dr. Thompson first saw him, three months afterward. He had then performed the operation advised by Dr. A. J. Gillette, using a bone-flap and a silver nail. At the end of a year the man could walk without a crutch or cane, and when seen about six months later, or shortly before his death from heart disease, there was free and painless motion to 90°, and the shortening was only three-fourths of an inch. Radiographs of the case were exhibited.

Neuroses as Seen in Orthopedic Practice.—Dr. B. E. McKENZIE, of Toronto, was the author of this paper. In it he reported nine illustrative cases which had been treated by systematic gymnastics. The line of treatment should be well defined, and the patient must be convinced not only by strong words but by the conduct of the surgeon that every detail of the treatment was essential. The least vacillation on the part of the surgeon would lead to failure. Class work in the gymnasium afforded a stimulus which should not be despised.

Hysterical Paralysis in Children.—Dr. L. A. WEIGEL, of Rochester, reported a case illustrating this disorder.

Dr. GIBNEY supplemented this with a clinical report of a case of anterior tibial pseudo-paralysis.

A Study by Means of the Radiograph of Six Cases of Osteitis Deformans (Paget's Disease). Dr. JOEL E. GOLDTHWAIT, of Boston, presented this paper. He said that he had come to the conclusion that osteitis deformans was not the rare disease it was usually supposed to be. This disease was not necessarily one affecting all the bones of the body. It was entirely different from syphilis, chronic osteomyelitis, osteomalacia, and other forms of bone disease associated with deformity. He thought it could be shown without question to be a diathetic disease. The disease embraced both an osteitis and a periosteitis. It must be differentiated from cases in which the joint itself is involved, and also cases of syphilis. All of the radiographs exhibited presented a peculiar striation or mottling of the bone.

Dr. WHITMAN was sure that hereditary syphilis attacks the interior as well as the exterior of the bone.

Dr. WEIGEL said that he had seen recently a case, apparently of hereditary syphilis, in which the entire exterior and interior of the tibia was involved. Contrary to his advice, an operation had been resorted to for the purpose of straightening the bone, and although this had been affected there had resulted in three days a gangrenous slough, and the gangrene was now spreading rapidly.

Multiple Pathological Dislocations of the Hip and Wrist. Dr. A. J. STEELE, of St. Louis, read this paper. He reported a case of double dislocation of the hip and wrist following typhoid fever; also several other cases of disease of the hip following fever.

A Case of Congenital Elevation of the Scapula Treated by Operation.—Dr. JOEL E. GOLDTHWAIT read this paper, and presented photographs. The operation had consisted in making a long incision obliquely over the scapula and turning back the trapezius muscle. The rhomboidei were represented by tense bands, and the levator anguli scapulæ was much shortened. These were cut away, and the shoulder was pulled down. The functional result was good.

Dr. GIBNEY reported a similar case in which he had successfully operated about nine years ago.

Dr. WEIGEL said that he had recently reported a case of spontaneous dislocation of the hip following typhoid fever. As the patient would not consent to operation he had made two ineffectual attempts to reduce the dislocation. A radiograph taken two years later showed that the head of the femur had been converted into a small knob.

Dr. WHITMAN said that about a fortnight ago he had operated and reduced a dislocation occurring two weeks after an attack of scarlatina.

Dr. C. L. STARR, of Toronto, commented upon the similarity of the muscular condition found in Dr. Goldthwait's case with that observed in torticollis.

Dr. McKENZIE said that he had recently seen a case of shortening of the trapezius and other muscles passing from the occiput to the cervical spine, acquired by years of assiduous practice on a violin.

Dr. A. M. PHELPS said that if the dislocation could not be easily reduced an excision was better. Operations on dislocated joints were very prone to result in suppuration and ankylosis.

Dr. A. H. FREIBERG, of Cincinnati, said that in 1899 he had reported a case of elevation of the scapula. The parents had refused operation at the time. A recent photograph showed how greatly the scoliosis had increased. He would divide these cases into groups; for example, one group would contain the cases in which there is synarthrosis between the scapula and the spine, and another would include cases in which the functions of the joint are normal but the scapula unusually high.

Report of a Unique Case of Dupuytren's Contraction—Operation by the Open Method.—Dr. FRANK E. PECKHAM, of Providence, made this report. He expressed a preference for the open method, as it made the surgeon master of the situation.

The Report of a Case of Abscess in the Posterior Mediastinum Occurring in Pott's Disease, Reached by Costo-Transversectomy.—Dr. J. E. GOLDTHWAIT made this report. A child of five years of age with Pott's disease of the upper dorsal region, and in poor condition, suddenly developed a type of difficult breathing which resembled ordinary croup. This continued for two days. Thorough examination failed to show anything in the throat itself. An abscess of the mediastinum was suspected, and accordingly an exploratory operation had been done. The abscess was found and evacuated, and the child was now convalescing rapidly.

Three other cases of abscess of the mediastinum had come under his observation, all presenting the same symptoms.

Dr. WHITMAN said that he had had two cases, and had noted in them a peculiar asthmatic breathing. In one of the cases it had been almost impossible to anæsthetize the child, in both the abscess had been located directly in front of the spine, making it very difficult of access.

A New and Rapid Method for Excision of the Hip-Joint. Dr. F. P. DOWNS, of Bridgeport, was the author of this paper. He said that excision was indicated earlier in feeble children and in those in poor circumstances. Aspiration never revealed the true extent of the disease. The curved incision should be made over the great trochanter down to the capsule, and the head of the trochanter should be removed and the acetabulum reamed out with the aid of the Doyen instrument. Little or no

hemorrhage occurs, and the operation lasts only a little over ten minutes.

Dr. S. L. McCURDY thought this instrument should prove useful for cutting bone in deep wounds, nevertheless it seemed to him too mechanical for use in eradicating diseased tissues. In a case of perforation of the acetabulum into the pelvis such an instrument might do a good deal of harm.

Dr. A. M. PHELPS said that the instrument had been designed for making a new acetabulum, and for this purpose it was perfect. It had occurred to him to extend its use to the removal of extensive disease of the neck and head, and he had found that its action was thorough and rapid. The danger of slipping into the pelvis was purely theoretical, for the operator selects successively larger sizes of the instrument as he advances.

Second Day—Wednesday, June 12.

A Brace for Anteroposterior Curvature of the Spine.—Dr. GWILYM G. DAVIS, of Philadelphia, exhibited a brace intended for convalescents. It had two uprights, one on each side, extending from the anterior superior spine to in front of the shoulder joint. The vertical piece was continued horizontally around the hips between the greater trochanter and the crest of the ilium, and pads were provided to make pressure just below the clavicles.

Osteoarthritis of the Spine.—Dr. JOEL E. GOLDTHWAIT made some remarks on this subject. He said that in this condition the back might be much deformed, or on the other hand it might be perfectly straight. He had found it perfectly possible to diagnose osteoarthritis of the spine in the beginning, and asserted that if proper treatment were instituted at that time marked deformity could be prevented. The patient often presented himself with pain in one leg, but instead of shooting along the whole trunk of the sciatic nerve the pain was referred to certain areas here and there. Frequently there was no pain in the back at all; at other times there was a characteristic pain which prevented the patient, on awakening, from changing the position in which he happened to be at the time. If the disease was in the lower dorsal region there would be a severe catching pain on coughing or sneezing. On account of the unilateral nature of the disease, motion was usually much freer on one side than on the other. The treatment of these cases in the early stage was most satisfactory, the affection yielding completely within a few months. It was not uncommon for most of the pain and disability to disappear in the course of four or five weeks. Tonics, stimulants, abundance of food and fresh air with absolute fixation of the parts, constituted the main features of the treatment—in other words, such measures as would be indicated for tuberculous conditions rather than for rheumatic affections.

Dr. RIDLON said that he had attempted to correct forcibly under anæsthesia three of these cases which had passed from the painful stage of rigidity. In the first case, that of a woman of twenty-five, the amount of straightening had been very great, and in the other two the improvement had been sufficient to make him feel that this treatment was safe and did not justify such a gloomy prognosis as had been hinted at by Dr. Goldthwait.

Dr. PHELPS presented, in connection with this discussion, a pathological specimen removed during an excision of a joint. When fresh, the specimen had been of an indigo-blue color, and Dr. N. Senn, who had been present at the operation, had pronounced the case one of osteitis deformans. He believed that rheumatism was nothing more than a germ infection or else some disorder of the nerve centers. He agreed with Dr. Goldthwait that these cases should be treated just as if they were tuberculous spines.

Dr. Goldthwait said he felt sure that some of his patients had been made worse by attempts to break up the rigidity, though he had frequently broken it up in cases in which there were atrophy and fibrous adhesions without bony ankylosis. He had used forcible correction under anæsthesia in osteoarthritis of the spine, but felt more inclined to do so after having learned of Dr. Ridlon's experience.

The Study of Muscular Expression as an Aid to Diagnosis.—Dr. L. A. WEIGEL, of Rochester, was the author of this paper. He referred particularly to those conditions of the muscles of the back and extremities which all orthopedic surgeons were accustomed to take into consideration in making the diagnosis.

Difficulties in Making a Differential Diagnosis in the Bone Lesions of Nurslings.—Dr. R. TUNSTALL TAYLOR, of Baltimore, read this paper. Cases were narrated to illustrate these difficulties, and the point was made that blood examinations should form a part of the clinical record just as did the urinary examination. This was particularly important in cases of bone disease because of the important part played by the bone marrow. Hereditary syphilis was perhaps the best known cause of a relative lymphocytosis in children.

Dr. R. W. LOVETT said that he had studied a good many cases of tuberculosis with reference to the blood count, and had been unable to discover any special relation between leucocytosis and tuberculosis. This conclusion had received the sanction of no less an authority than Dr. Richard Cabot. In the diagnosis of joint diseases in young children he had experienced difficulty in differentiating the nutritive disturbances occurring around the epiphyses.

Dr. MCCURDY reported a case to emphasize the position taken by him a few years ago relative to syphilis as a cause of many of the bone affections of early life.

Dr. W. R. TOWNSEND, of New York, remarked that it was well to remember that under the age of two years tuberculous lesions are comparatively rare while syphilitic disease of bone is relatively common.

Dr. RIDLON said that he wished once again to assert that all cases of multiple joint disease should be suspected of being syphilitic.

The Treatment of Abscesses of Tuberculous Bone Lesions.—Dr. CLARENCE L. STARR, of Toronto, presented this paper. He said that for practical purposes a tuberculous abscess should be looked upon as a tuberculous cyst rather than as an abscess, because most of the distinctive features of an abscess are wanting. Under no circumstances should the let-alone policy be adopted where a tuberculous abscess had already led to reddening of the skin. Aspiration seemed to serve no useful purpose. He did not consider it wise to incise and drain an abscess except when urgent symptoms were present. Complete excision of an abscess was theoretically the proper treatment, but the method was applicable to only a few cases. The plan which had given him the best results consisted in free incision or incisions, scraping of the wall, and complete closure of the wound or wounds. He had not had a single case of general infection following this treatment. The whole cavity might be swabbed out with pure carbolic acid after the scraping and before the closure of the cavity. In nearly all cases primary union occurred, and the cavity was obliterated. Following the suggestion of Tubby, he had adopted the plan during the past year of flushing the cavity with a solution of one drachm of menthol in one ounce of methylated spirit, and the results had been most satisfactory. This plan of treatment was applicable in a general way to tuberculous abscesses in any situation. In the cervical region the abscess should not be evacuated ordinarily through the pharynx because of the danger of mixed infection. Abscesses from the last dorsal or first lumbar vertebra will point beneath Poupart's ligament. Incision should be made as far as possible away from the groin, preferably on the outer side of the thigh.

Dr. R. W. LOVETT said that some years ago he had sutured the wounds after opening a number of hip abscesses, but most of them had broken down afterward and had been worse than before; yet if these abscesses

were left open they undoubtedly became infected in spite of all precautions. He had reported a series of cases of psoas abscess occurring from 1890 to 1900. The mortality in the first five years had been 50 per cent. and in the last five years, 25 per cent. In all but four cases the treatment had been by incision. He believed that about 50 per cent of psoas abscess cases would result in recovery, and he was skeptical regarding the advisability of stirring up the pyogenic membrane of tuberculous abscesses. When he had employed both a lumbar and an iliac incision the mortality had been greater than when, as for the past two years, he had used simply iliac incision. His results with the early removal of the drainage tube had not been good, so it was his custom now to leave it in for about two weeks.

Dr. A. M. PHELPS said that all psoas abscesses should be opened and washed out under high pressure, and then a drainage tube shall be introduced up to the point of disease. Aspiration was worse than useless, for it lulled one into a feeling of false security. It was imperatively necessary to open the abscess and introduce the finger for purposes of exploration. It was a mistake to wash out the abscesses with sterile water; they should be washed out first with pure carbolic acid and then with alcohol. Gauze should be avoided, as it acted as a plug. If extensive curetting were done in a psoas abscess and a focus of disease still remained, the whole surface would become infected. It was a good rule never to scrape a sinus or abscess when there was dead bone at the bottom.

Dr. H. A. WILSON remarked that some of these tuberculous abscesses undoubtedly disappeared without evacuation. In his own experience, when abscesses had been incised and let alone, the patient being kept in bed, the abscesses had not done well and the patients had emaciated; on the other hand, when apparatus had been applied and the patients allowed out doors sinuses had been avoided. The primary object of treatment should be to develop the constitutional condition of the patient and improve the reparative process, and if this were done operation would often be unnecessary.

Dr. A. J. STEELE, of St. Louis, said that his treatment consisted in thoroughly emptying the abscess and then repeatedly injecting with a hard rubber syringe water at a temperature higher than could be borne by the hand. The results had been remarkably good, and when the disease was not active he expected prompt cure.

Dr. FRANK E. PECKHAM, of Providence, said that Dr. Steele had struck the keynote in the statement that everything depended in these cases upon whether or not pus formation had ceased. He had employed for some time past the method of treatment described in the paper. It was important that the abscess cavity should be obliterated by the use of a very tight compression bandage. He had never seen any emaciation or other trouble arise from keeping the patient in bed for a month.

Dr. JOHN RIDLON declared most emphatically that abscess was a mere incident in connection with tuberculous disease, and was not of the slightest importance. He had tried hot water, carbolic acid, and other irrigation fluids, and had discarded them as useless. When not operated upon these cases do not present bad symptoms; then why disturb them and make them sick? If a deep and inaccessible spinal abscess were left without operation and the patient escape with his life, then why not adopt the same course in the management of other and more superficial abscesses? All these abscesses close if left alone; hence, it was a matter of little importance if they remained open a few months, or even a year or two, provided the patient's general condition was satisfactory. This let-alone policy had been his method of treating these abscesses for twenty years, and his patients had recovered; hence, he felt that he had a right to speak with some emphasis in favor of the plan, particularly as he had also tried the operative treatment, and had found it unsatisfactory

Dr. E. K. ROOT, of Hartford, said that the remarks of the last speaker exactly coincided with his own views. He had seen many cases of tuberculous abscess end in spontaneous recovery, and he believed if a small quantity of pus could be absorbed, so also could be a larger quantity.

Dr. G. G. DAVIS also endorsed Dr. Ridlon's position, asserting that it was wrong to apply the rules of general surgery to orthopedic surgery. Dr. Phelp's method was perfectly applicable when one could eradicate the bone lesion, but not otherwise. He was not in favor of interfering with psoas abscesses except in a few rare instances, in which the psoas abscesses caused fever and intense pain. The cases of death in connection with tuberculous bone disease had, as a rule, been those in which there had been long-standing discharging sinuses.

Dr. L. A. WEIGEL said that he had treated tuberculous abscesses both by the operative and non-operative plan, and was compelled to take exception to Dr. Ridlon's statement, that all patients with tuberculous abscesses get well whether treated or not.

Dr. C. L. STARR, in closing the discussion, said that one point in favor of his method of treatment was that in the cases of amyloid disease coming under his care, there had always been a mixed infection and a discharging sinus. It had certainly not been his experience that tuberculous abscesses were of no importance, and to his patients, at least, it made considerable difference whether a discharging sinus remained for two months or two years. When the abscess was increasing in size and threatened to break down, it seemed to him criminal to allow it to go on and do so. The pus formation came in large measure from the abscess wall, and not from the focus of disease. As a psoas abscess was often made up of numerous pockets, it was obviously impracticable to pass up a drainage tube to the seat of the disease. If a tube must be put in, the earlier it was removed the better.

Deformity Arising from Injury to the Lower Epiphysis of the Tibia.—Dr. B. E. MCKENZIE presented a cast and reported a case of this kind occurring in a child of two years as a result of caries. When the child, then at the age of about ten years, was seen by him, he had operated, removing the epiphyseal cartilage but not the epiphysis of the fibula. Growth, he had reasoned, would naturally not continue for more than about ten years longer, and unless this had been done the deformity would have recurred. The operation had been done ten years ago and the boy still had a good foot.

Dr. COOLIDGE, of Chicago, said that one could get along fairly well with a certain lengthening of the leg from the growth of the tibia, and it seemed to him better to do this than stop the entire growth of the lower epiphysis.

Drs. G. G. DAVIS and A. H. FREIBERG reported similar cases.

A Hip Splint.—Dr. JOHN DANE, of Boston, was the designer of a new hip splint, which in his absence was exhibited by Dr. Lovett. Reference was made to some experiments by Dr. Dane on the fixative power of the traction splint. In several experiments the amount of motion had been found to be from 16° to 27°. The splint presented showed a possibility of only about 6° of motion. The lower portion was the same as in a former splint that Dr. Dane had devised and described, but an additional feature was an extra pelvic band.

The Treatment of Acute Hip Disease with the Exhibition of a Splint.—Dr. R. W. LOVETT, of Boston, read a paper with this title. He said that cases treated by traction do not show as much wearing away of the femur as those treated without it, and it had been demonstrated clinically that traction adds much to the comfort of the patient. With the traction should be combined enough fixation to limit the play of the joint to the arc set by nature in the development of reflex spasm. The splint presented resembled closely the Lorenz splint. Fixation was secured by the use of the traction splint combined

with a plaster of Paris spica reaching up to the axilla. After the acute stage had subsided the plaster spica was used as a mold for making the leather attachment. Cases of hip disease permitting not over 15° of motion should be treated by the best obtainable fixation plus traction. Treatment by recumbency was not generally necessary if this apparatus were applied to the hip in the position of deformity—in fact, this ambulatory treatment sometimes seemed to be superior to recumbency. The splint should be removed as seldom as possible. Cases allowing from 15° to 45° of motion should be treated by Dane's hip splint with high shoe and crutches. The use of the ordinary traction hip splint he believed should be limited to cases allowing 45° of motion, and should be employed in connection with a high shoe and crutches.

Dr. ROYAL WHITMAN said that as long ago as 1892 he had applied a plaster spica beneath the ordinary hip splint, and had used this method more or less ever since. He believed thoroughly in combining traction and fixation in the treatment of hip disease, and rejected the notion that one might allow of motion to the limit set by nature. The ordinary hip splint allowed 15° or 20° of motion, and, in the majority of cases, this gradually diminished until, as shown by Drs. Shaffer and Lovett, it was altogether lost. Dr. Dane's splint was superior to the ordinary traction apparatus in that it gave better fixation.

Dr. RIDLON said that some years ago he had embraced the doctrine of fixation as opposed to the use of the long traction splint with limited motion, but of late years he had modified his views somewhat, and now laid it down as a safe rule, that whatever would most radically relieve the pain and muscular spasm should be the form of treatment to be employed. The great point was to secure the fullest possible hyperextension.

Dr. WALLACE BLANCHARD, of Chicago, said that eight or ten years ago he had presented a splint intended to immobilize and at the same time produce traction in the axis of the neck of the femur. He was glad to note the present trend of opinion in favor of using both traction and fixation.

Dr. G. G. DAVIS said he was glad that the use of two side-irons in the hip splint was gaining ground, but when such a degree of fixation was required as was indicated by Dr. Lovett's brace he would be disposed to keep the child in bed.

Dr. COOLIDGE referred to two cases in which the use of a spica in combination with the Thomas splint and traction had acted very well.

Dr. PHELPS claimed that the braces of Dr. Dane and Dr. Lovett were practically the same as had been in use for years in the New York Post-Graduate School.

Dr. Lovett dissented from this opinion, and said the splint had been designed with a full knowledge of the Post-Graduate splint, and differed from it materially.

Treatment of Non-Infected Sprains and Contusions by Forcible Manipulation, with Continued Free Use, Versus Partial or Complete Immobilization and Rest of the Part.—Dr. ARTHUR B. HOSMER, of Chicago, read a paper with this title. He said that since 1892 he had treated all his patients suffering from sprains or contusions according to the method advocated. The acute cases had required from one to fifteen manipulations, whereas chronic cases had often required upwards of fifty treatments, and he was accustomed not to accept the treatment of such cases in this way unless the patients were willing to come daily for three months. The method consisted in jerking, kneading, pinching, and hammering the parts. The hammer which he used was made of a leather finger-cot containing shot, and its solidity might be increased or decreased by means of an adjusting screw. Dr. Hosmer detailed an interesting and original series of experiments on the legs of rabbits in which trauma had been produced by the falling of a bag of shot under suitable conditions. The idea was to show the effect on injured limbs of manipulative treatment after traumatism. The animals were killed at a varying length of time after the injury, and the condition of the tissues was noted post mortem. Several rabbits' legs were exhibited to illustrate the points made.

Dr. G. G. DAVIS raised the question as to whether this treatment was applicable to that class of cases in which, although the ordinary symptomatology of sprains was present, the *x*-rays reveal the splintering off of pieces of bone.

Dr. PECKHAM said that for some years he had treated sprains by massage, hot air, and the use of a stockinette bandage, and had found that under this treatment a person with even a severe sprain would be able to go to work again within a week.

Dr. R. H. SAYRE said that from his personal experience he was in favor of immobilizing a sprain immediately after the injury rather than subjecting the injured part to manipulation.

Dr. MCKENZIE said that while theoretically sprains should be treated by rest at first, he was disposed to think that the results of massage were superior.

Traumatic Kyphosis of the Spine Due to Rupture of the Spinal Ligaments.—Drs. CHARLES F. PAINTER and R. B. OSGOOD, of Boston, presented this paper, which was read by Dr. Painter. They reported three cases of injury to the spine accompanied by rupture of the ligaments without luxation or fracture. Their conclusions were: (1) That the spinal ligaments during life may be ruptured without fracture or dislocation; (2) that nerve-pressure symptoms may occur from simple flexion of the vertebral column; (3) that recovery in these cases requires prolonged rest in a position which favors repair of ligaments; (4) that the force which commonly produces the injury is one which *a priori* would be most likely to produce ligamentous rupture. There was no suggestion of thickening of callus in any of the cases reported. The first two cases would seem to disprove the theory that they were ununited fractures because one patient had been in bed convalescing from an amputation of the arm, and the other was convalescing from a tedious fracture of the leg. In all of the cases found in literature, with one exception, in which there was a record of the manner of production of the injury it had been the same. The cases referred to in the paper were characterized by an absence of deformity immediately following the injury. As a rule, the injury became apparent only after the patient got up a considerable time afterward.

Drs. ROOT, PECKHAM, GOLDTHWAIT, MCKENZIE, and SAYRE also reported cases.

The Relative Merits of Osteotomy and Forcible Correction in Deformities at the Hip and Knee.—Dr. V. P. GIBNEY, of New York, read this paper. He said that osteotomy was often preferable to the application of a strong force with division of tendons and the like. It had seemed to him that when there was even a fair range of motion in the hip it was better to do an osteotomy, not that he was afraid of producing injury, but because he preferred an osteotomy between the trochanter major and trochanter minor and putting the limb straight, with the idea of securing a more lasting result.

An Apparatus for the Study of Scoliosis.—Dr. ROBERT W. LOVETT exhibited a simple apparatus for measuring and recording lateral curvature.

The Treatment of Scoliosis by Forcible Jackets.—Dr. LOVETT also read this paper. The chief object of treatment, he said, was to produce an extended position of the affected part of the spine, because the rotation of the extended position is the reverse of the rotation in the flexed position. To accomplish this he had applied forcible jackets with the patient lying prone on the hammock. There were two holes in the hammock through which his legs hung vertically. The lumbar spine was perfectly level. Heavy padding was applied over the hip, and the jacket was carried as high as de-

sired. Care was necessary not to use too much side pressure. He had changed these jackets at intervals of from three to ten days, and the best results had been when the interval had been from five to eight days. Only bad cases with fixed bony curves and marked bony rotation had been subjected to this treatment. The author detailed experiments that he had made on a scoliotic cadaver from a person about forty years of age. Flexion and hyperextension made a difference of five inches in the length of the spine measured along the spinous processes. Corrective side pressure seemed more efficient in the prone than in the suspended position. He had been struck with the greater mobility of the spine in the prone than in the suspended position. Careless attempts to diminish the rotation in a fixed curve result in an increase of the lateral deviation. If forcible correction were to be employed it should be antagonized in such a way that it would be expended on the thorax and not be dissipated through the spine. Suspension in stiff spines was a measure of comparatively little value. Lateral force was less effective when applied in suspension than in the prone position. When there was much rigidity the force could be applied to the curve itself accurately by means of an apparatus, or by changing the curved regions as a whole in relation to the spine. Both of these methods were desirable, but they should be separated in one's mind

The Proper Adjustment of the Clothing as a Part of the Treatment of Faulty Attitudes of the Spine and Shoulders.—Dr. JOEL E. GOLDTHWAIT, of Boston, was the author of this paper. He said that most of the ready-made clothing in children is so arranged that the weight comes on the shoulder, and the stocking straps are largely made to fasten either to the waist or to special shoulder straps, all of them coming well toward the outer portion; hence the weight comes on the tip of the shoulder, the part least capable of carrying weight. The result was that when the stocking straps were buckled up there was a weight of two or three pounds coming on the tip of the shoulder, and consequently the shoulders drooped forward after a time, and the stoop shoulder with the "angel wing" scapula was a common result. The child can stand any amount of pressure provided it is placed near the neck. This should be the arrangement of the clothing for children, very much as it is with properly adjusted suspenders in men.

Dr. A. M. PHELPS said that his anatomical specimens showed that if one ever expected to increase the compensatory curves the entire thorax must be changed. He believed that treatment in the future would be directed to making compensatory curves both above and below the primary curves.

Dr. WHITMAN cited a case of congenital rotary lateral curvature of extreme degree which he had had under observation and treatment for about six years. The child had been treated by plaster jackets, and the rotation and lateral deviation had been almost entirely corrected. Dr. Phelps' argument from adult spines was not applicable to orthopedic practice, which is concerned chiefly with young children.

Dr. A. H. FREIBERG, of Cincinnati, said that he had taken many photographs, by short exposures, of cases of scoliosis, sometimes almost daily, and had been surprised to note the great variations in the curves. It was also evident that it was an error to take the spinous processes as an absolute measure of the rotation or lateral deviation.

Club-Hand with Congenital Absence of the Radius; Plastic Operation. Dr ROSWELL PARK, of Buffalo, reported this case. He had, by operation, impaled the carpus upon the ulna, and had transplanted a fragment of the humerus of a rabbit into the gap. The result had been successful.

Operation in Severe Case of Spasmodic Wry Neck.—Dr. PARK also reported this case. So far as could be ascertained, this spasm of the muscle was the effect of an arsenical neuritis. He had first practically extirpated the sternomastoid and a large V-shaped piece of the trapezius, and had freely divided the trapezius on the side towards which the head was inclined. For a few weeks there had been marked improvement, but the patient soon returned nearly as bad as before. He then extirpated most of the left sternomastoid, and divided the contracted levator anguli scapulæ. The omohyoid was found to be exceedingly tense, and so it was divided, together with other shortened aponeurotic structures. The head then came fairly well into position, and was so held in plaster of Paris for a week. At this time the wounds had completely healed. The ultimate result was good. This was the worst case of torticollis that he had ever encountered, and the operation was the most extensive of its kind on record. The operation seemed to him to bear some analogy to the graduated tenotomies done by the oculists.

Dr. WILLIAM J. TAYLOR, of Philadelphia, remarked that he had assisted Dr. W. W. Keen in a similar operation some years ago. Both sternomastoids were removed by operation, yet the man had complete control of the movements of his head.

Dr. S. L. MCCURDY, of Pittsburg, said that he had reported in the *Transactions* for 1893 a case in which he had done on the carpus an operation similar to that just described by Dr. Park.

Further Observations on Rapid Osteoclasis for the Correction of Rachitic Deformities of the Legs.—Dr. WALLACE BLANCHARD, of Chicago, read this paper. He reported on 260 cases of bow legs, knock-knees, and anterior tibial curves, and in not a single case was there any abrasion of the soft parts, in none was there delayed union, or, so far as known, any epiphyseal separation. He insisted that these crooked legs must be put up in the highly overcorrected position. He thought the time had passed when more than six weeks should be taken for the perfect correction of the majority of these deformities. In eighty per cent. of the cases in which the children came to him wearing braces, the bones had become so consolidated that nothing short of fracture or osteotomy could accomplish anything. The bones were usually not sufficiently consolidated in cases of rachitic curvature to justify osteoclasis until the age of six years, though occasionally there was sufficient consolidation at the age of four years. He used the original Grattan osteoclast, and operated with the utmost confidence, never taking more than eight seconds for the operation. In cases of anterior double curves, a lateral break must first be made, and often it was necessary to cut the tendo Achillis.

Third Day—Thursday, June 13th.

Fat Embolism in Orthopedics.—Dr. F. S. COOLIDGE, of Chicago, read this paper. He reported two cases. The first was that of a man bedridden with chronic rheumatism. The knees were straightened, and an impacted fracture occurred under the simple manual force employed. Soon after coming out of the ether, the man began to suffer from dyspnœa, and became cyanotic, and in twenty-four hours was dead. The second case was that of a man of twenty-four years who had been paralyzed for two years. An operation had been undertaken to straighten his knees. While extending the foot prior to a tenotomy of the tendo Achillis, he had been surprised to detect crepitus and an impacted fracture of the tibia. This accident was quickly followed by the development of cyanosis, intense sweating, a rapid pulse, and great restlessness. After two days, these symptoms disappeared. The author stated that in both instances the fracture produced by manual force had been of such a nature as to indicate that the bone was the seat of fatty degeneration, and he believed this was the essential point in the production of fat embolism.

Dr. CLAYTON, of Brooklyn, reported a case of fat embolism occurring in a little Italian child after he had done a Macewen osteotomy for the correction of rachitic knock-

knee. The temperature reached 108° F. before death, and the existence of fat embolism was proved at autopsy

The Typhoid Spine.—Dr. WILLIAM J. TAYLOR, of Philadelphia, presented in this paper the report of one case in order to reconcile certain discrepancies that had appeared in the reports of cases claimed to be examples of the typhoid spine. Dr. Keen believes that it is merely a functional neurosis, and Osler expresses the opinion that it always occurs in neurasthenic individuals. His patient was a man of twenty-seven, who developed typhoid fever on February 4, 1899, and was in bed for nine weeks. After having been out of bed for a few days he began to suffer from pain along the spine, chiefly in the lumbar region. The temperature ranged from 102° to 99°F. Every time the abdomen was exposed for a physical examination there developed a peculiar rhythmical tremor of the abdominal wall. It was true that the man presented certain stigmata of hysteria, but there was evidently a distinct lesion of the spine. He left the hospital cured early in September. When examined some months later the thickening previously observed in the lumbar region had disappeared.

Dr. FREIBERG also reported a case occurring in a boy of sixteen years. The pain had been at once relieved on placing the patient upon a plaster bed in the prone position. After about one week of this treatment the temperature fell to normal, and the pain had almost wholly abated.

The Treatment of Spastic and Other Forms of Paralysis.—Dr. A. M. PHELPS, of New York, was the author of this paper. His remarks were confined to a consideration of infantile paralysis, spastic paralysis, Pott's paralysis, and paralysis following fractures. In infantile paralysis, he said, there was paralysis of groups of muscles. It was generally conceded that this variety of paralysis was the result of infection. If treatment was neglected, contractions were bound to take place. In spastic paralysis all of the muscles were affected, and the stronger muscles, antagonizing the weaker, produced the deformity. In infantile paralysis one group of muscles was paralyzed, allowing the other muscles to act. If treatment were begun at the onset of the paralysis by proper bracing, the occurrence of deformity could be largely prevented, and if braces were not sufficient, tenotomy should be resorted to. When there was total paraplegia a stiff rod should be used so as to make the body and one limb one piece, and on the other side should be a brace with an automatic catch. The stops should be placed anteriorly so as to prevent flexion. At the age of sixteen excision of the knee should be performed. In his own experience he had found braces of absolutely no use in spastic paralysis of the severer forms. The lesion in these cases was located in the lateral columns of the cord, or more commonly in the vertex of the brain. His method of treatment was to make an incision and divide the hamstrings and the adductor muscles, and then apply suitable braces. One occasionally met with cases of Pott's paralysis in which the condition became progressively worse. When incontinence of urine and fæces was present and was becoming worse, he believed the sooner laminectomy was done the better. This operation was not especially difficult, and he had never regretted having done it. In cases of fracture of the spine producing paralysis, rest in bed should be insisted upon for a week, and if the patient survived, an operation should always be done.

Dr. RIDLON said that, in cases of spastic paralysis, he now made use of plaster for a few weeks only after division of the foot tendons and hamstrings. It was wiser to operate upon the latter by open incision.

Dr. G. G. DAVIS said that in recent years arthrodesis and transplantation of tendons had been brought forward as substitutes for braces. He did not feel justified in doing arthrodesis on the knee-joint, preferring a brace with a lock-joint. He thought in time braces would be largely discarded in these cases, and they would be treated by various operations for tendon transplantation

Dr. W. R. TOWNSEND, of New York, thought teachers should lay greater stress upon the necessity for bringing cases of infantile paralysis to the surgeon so early that deformity might be prevented.

Dr. Phelps, in closing, said that the severer forms of spastic paralysis must certainly be treated by braces In infantile paralysis subcutaneous tenotomies were alone sufficient. He had found the results of tendon transplantation so disappointing that he had entirely discarded this method.

The Operative Treatment of Confirmed Paralytic Talipes of the Calcaneus Type.—Dr. ROYAL WHITMAN, of New York, read this paper. He said that the disability of calcaneus depends largely upon the insecurity of the foot The most effective remedy, therefore, was the removal of the astragalus. The operation that he had found the most useful comprised astragalectomy, arthrodesis, tendon shortening, tendon transplantation, and backward dislocation of the foot. The operation was most conveniently performed under the Esmarch bandage. He had performed thirteen of these operations, and in none had there been any infection. Although the cartilage was removed from the bones, absolute ankylosis should not be expected and was not desirable. In all cases apparatus had been used to prevent deformity.

General Remarks on Painful Affections of the Feet.—Dr. FRANK E. PECKHAM, of Providence, in this paper said that heat alone without massage was of the greatest benefit just prior to the employment of gymnastic exercises. In none of his cases had the massage been done by a professional. The exercises which had given him the most satisfaction were those recommended by Dr. Whitman, the patient being seated and the leg across the stool. Several cases were reported in which painful feet had been associated with glycosuria.

Dr. WHITMAN remarked that if pronation were increased by the tiptoe exercise it was evidence that the exercise had been improperly given, for the feet should be turned in.

Drs. WILSON, LOVETT, and RIDLON detailed their experience with pupil nurses who suffer severely, especially during the probationary period, from painful feet. Dr Lovett noted that these cases were apt to develop after attacks of diphtheria, tonsillitis, typhoid fever, and scarlet fever. Dr. Ridlon was convinced that in many of these cases there was an underlying autotoxæmia They were often completely relieved by taking every night a dose of a freshly made infusion of senna sufficient to secure a good daily evacuation of the bowel

Dr. BALDWIN, of Salt Lake City, exhibited a little brace made of wood that he was accustomed to use as a support to the arch of the foot, each brace being made for the individual case.

Dr. WEIGEL called attention to the fact that there was a set of symptoms, generally called rheumatic, which disappeared, even from other parts of the body, when the foot was relieved. He was accustomed to use static electricity in addition to mechanical support for the feet.

Dr. C. L. STARR thought that in the so-called rheumatic conditions there was probably a partial dislocation of certain tarsal joints, associated with more or less inflammation.

Caries of the Spine—An Analysis of One Thousand Cases.—Dr. CHARLES H. JAEGER and Dr. J. H WATERMAN, of New York, presented this paper. Of the cases studied, 600 children were in the first year of life; in 6.6 per cent. the disease was cervical; in 70.9 per cent. dorsal, and in 20.9 per cent. lumbar. In over ten per cent. of the cases the parents were tuberculous. Abscesses were recorded in over fifteen per cent. of the cases in the first ten years of life. Careful inquiry seemed to indicate that traumatism was the exciting cause in 298, and infectious disease in forty-two cases.

Coccydynia—Case and Specimen.—Dr. A. R. SHANDS,

of Washington, D. C., said that this title had been selected for the report because his diagnosis had been coccydynia, although the case had proved to be one of caries of the coccyx. The spine was normally flexible, but throughout entire length was tender, and the woman presented marked evidences of hysteria. The speaker's first diagnosis had been hysterical spine. Subsequently it had become evident that the trouble was located in the coccyx, and on his advice this bone had been removed. The specimen was exhibited. It showed a condition of caries with a number of osteophytes. The patient had been markedly improved, but had died four months later of another disorder.

Some Experiences in the Bloodless Reduction of Congenitally Dislocated Hips.—Dr. JOHN RIDLON, of Chicago, read this paper. He said that he had seen in Chicago thirty-seven cases, and had practiced the bloodless method of reduction in sixteen. Of these sixteen the bone had remained permanently in place in six cases. He had known the bone to go out of place after having remained in position for a year or more.

Dr. PHELPS said that although he had operated upon over one hundred cases by the bloodless operation of Hoffa in only four or five cases had he found a proper socket for receiving the head of the bone. He did not believe the head would make a new socket for itself.

Dr. WHITMAN said he had succeeded in curing a number of patients by the forcible manipulations advocated by Dr. Ridlon, though he had not succeeded in securing so large a percentage of permanent reductions as had this surgeon. If the head of the bone were in place, it should be felt clearly beneath the femoral artery.

Dr. HOSMER favored the use of a modification of Allis' apparatus to secure good fixation of the pelvis.

Officers Elected.—*President*, Dr. H. A. Wilson, of Philadelphia; *First Vice-President*, Dr. William J. Taylor, of Philadelphia; *Second Vice-President*, Dr. Gwilym G. Davis, of Philadelphia; *Secretary*, Dr. John Ridlon, of Chicago; *Treasurer*, Dr. E. G. Brackett, of Boston. The next annual meeting will be held in Philadelphia.

SCHOOL FOR HEALTH OFFICERS.

Third Annual Meeting, Held at Burlington, Vt., July 8–11, 1901.

C. S. CAVERLY, M. D., OF RUTLAND, VT., PRESIDENT.

THIS convention, which had its headquarters at the State Laboratory of Hygiene, was held at the call and under the supervision of the Vermont State Board of Health. Dr. C. S. Caverly, President of that Board, called the meeting to order, and gave a brief review of health legislation in the State of Vermont. As an incentive to continued efforts in connection with public sanitation, the speaker quoted statistics for the five years prior to the establishment of the State Board of Health, in 1886, and for the last period of five years of which complete statistics were at hand, *i. e.* 1895 to 1899. Thus, in the former period there was an average annual death rate from scarlet fever of sixty, and in the latter period of two, or a reduction of 96 per cent. In the first period there had been an annual death rate from diphtheria and croup of one hundred and ninety-one, and for the second of ninety-four, or a reduction of 50 per cent. Again, in the first period the average death rate from general and pulmonary tuberculosis had been seven hundred and forty-nine as against five hundred and eleven in the second period, or a reduction of about 31 per cent. Measles was the only one of the infectious diseases that showed an increase during the second period, and here the advance had been 21 per cent. It was also worthy of note that these statistics showed measles to be almost as fatal a disease as scarlet fever. As significant of what should be the trend of future work, attention was directed to the fact that there had been an increase in the number of deaths from pneumonia of 13 per cent., from heart disease of 30 per cent., from kidney disease of 29 per cent., and from cancer of 129 per cent.

Dr. DAVID C. HAWLEY, Mayor of Burlington, delivered the address of welcome. In it he pointed out that sanitary laws were a public necessity, and asserted that as such they should be rigidly enforced. The dangers of tuberculosis were made clear, as well as the great value of isolation of cases, disinfection, destruction of the sputum, and the establishment of state sanatoria. The speaker classed inebriety as a disease, and expressed the opinion that it should be placed under state control, and that its victims should be treated in reformatory institutions.

Governor W. W. STICKNEY, of Ludlow, also delivered an address, in which he discussed the question of a federal board of health, and upheld its legality on the ground that whatever subserves the health of the people has always been considered legal by the highest courts. Vermont, he said, had cause to be proud of her position as one of the leaders in sanitary legislation.

Senator J. A. DEBOER, of Montpelier, made some remarks from the point of view of one who was neither a health officer nor a physician. He said that sneers at the science of sanitation were out of date, for splendid progress had been made in this field, and that too in the direction of greater intelligence and morality. He declared that the matter of health touched one every too closely to permit of the knowledge of its laws being the property of a few, and for this reason it was most important that a strong effort should be made to popularize this science.

In Memoriam. Dr. Jo. H. Linsley.—Dr. CAVERLY read a sketch of the life of the late Dr. Jo. H. Linsley, formerly of New York City, who had done so much for sanitary science in the State of Vermont. It was through his influence that bacteriology had taken such a prominent part in sanitation in that State; it was he who had made the State Laboratory possible, and his earnest, enthusiastic, and conscientious work in this field would ever be a worthy monument to him.

Laws Relating to Public Health.—Col. JOEL C. BAKER, of Rutland, read this paper. He said that the ten commandments were not older than sanitary laws. Every man owed a duty to society not to imperil the life and health of others, and the State had the right to enforce sanitary laws, even to the point of interference with personal and property rights, provided always that they subserve the interest of the public health. The State Board of Health had adequate power with regard to the control of contagious diseases, but the same could not be said concerning other matters properly coming within its jurisdiction.

Health Officers, Their Duties and Responsibilities.—Mr. H. L. STILLSON, of Bennington, in this paper pointed out that the modern health officer had important and varied duties, and that his education should be such as to give him a good working knowledge of law, medicine, physics, engineering, and last but not least, of human nature.

Dr. L. M. GREEN, of Bethel, said that much sickness would be avoided if each town would continually watch its water supply, and from time to time have the water examined at the State Laboratory.

Sanitary Legislation.—Dr. W. N. PLATT, of Shoreham, was the author of this paper. He argued that as no other State had an absolutely free state laboratory or a state board of health possessed of such extensive powers, it was incumbent upon Vermont to see that her health officers had exceptionally good opportunities for instruction. To this end he suggested that the University of Vermont should give a course leading to a degree in medical sanitation. Continuing, he urged the complete isolation of contagious diseases and the establishment of an institution for the free treatment of tuberculosis.

Relation of Animal Diseases to Public Health.—Dr. Don. S. Grout, of Waterbury, read a paper on this subject. He enumerated the following diseases of domestic animals as being those which are known to be communicable to man: (1) Glanders and farcy; (2) rabies; (3) malignant anthrax; (4) tuberculosis; (5) malignant cholera; (6) milk sickness; (7) smallpox; (8) diphtheria; (9) scarlet fever; (10) possibly typhoid fever in suckling animals, and (11) the plague, which is a disease so common to man, monkeys, and rodents that it is a question whether it was primarily a human disease or a rat pest.

Human *glanders* is a most loathsome and fatal disease, which is usually contracted from the horse or mule by accidental inoculation into wounds. It is most common where the horse is most extensively used, and has been epidemic in Montana and some other Rocky Mountain states.

Malignant *anthrax* is very deadly whether it shows itself in the form of malignant pustule or internally as carbuncular sore throat or intestinal anthrax. It prevails mostly among butchers, tanners, and workers in hair, but may occur as a result of eating the flesh of infected animals. Infection by simple contact, without break in the skin, is by no means uncommon. Cooking is a very insufficient protection; frost does not kill the virus, and infected pastures have been known to maintain their infecting qualities for six years in succession, and to yield hay which continued to infect animals when fed to them at a distance from such pastures.

Milk sickness, or "the trembles," is so largely a disease of the backwoods districts that many medical men are disposed to doubt its very existence. It resembles anthrax in its communicability to other animals, but differs essentially in that it fails to show local anthrax lesions. It is said to be associated with the presence in the blood of a microbe like that seen in relapsing fever, and this germ is probably derived from drinking water or from the surface of certain kinds of vegetation. It is as fatal to man as to animals, and in persons who survive the attack it produces a condition of great hebetude and physical weakness.

Turning to the consideration of *tuberculosis*, the speaker said that statistics show that from five to eight per cent. of the cattle in our Northern states suffer from this disease. From the first scientists had generally believed that the species of bacillus found in man was identical with that in cattle, and that the apparent difference probably arose from the difference in environment. It had been demonstrated that the tuberculous material from man might produce the tuberculous disease in cattle, and many instances pointed to the conclusion that the disease might be transmitted from cattle to man. If these facts were well established there could be no longer any question about the identity of the bacillus in man and animals. Dr. E. F. Brush, of Mount Vernon, N. Y., was quoted as believing that human tuberculosis was derived from the bovine species, the argument being that among the Esquimeaux, who have no dairy cows, pulmonary phthisis is not known. Dr. Brush endeavors to explain the fact that tuberculosis is not more frequently communicated from cattle to man on the theory that the bacillus introduced from the cow into man finds a difference of four or five degrees in body temperature, and that it does not become virulent in man until from some other cause the temperature is increased and allows of the multiplication of the bacilli. Tubercle bacilli would grow in the cow without any disturbance of her normal temperature, and this seemed to explain why cattle apparently enjoying good health are found when slaughtered to be in an advanced stage of tuberculosis. The spreading of the bacilli from the nests or tubercles was undoubtedly the consequence of an alteration of the general health. In considering the all-important problem of the prevention of tuberculosis, one must recognize that disease of the udder of the cow is particularly dangerous because the milk though infected may appear normal for some weeks. Dr Harold C. Ernst, of Massachusetts, was quoted as saying that there was no ground for the assertion that there must be a lesion of the udder before the milk could contain the infection of tuberculosis, and that the germ might be present in the milk from cows affected with this disease in any part of the body, and that they were indeed present and active in a very large proportion of cases in which there was tuberculosis but without lesion of the udder. But aside from this question of the existence or absence of a lesion of the udder, it should be remembered that in a large proportion of tuberculous cattle the disease is present in the gastro-intestinal tract, and the bacilli are thrown off in the dung, and the latter, drying on the animal, is very likely to get into the milk. For this reason it seemed to him doubtful if a pail of milk ever left a stable where tuberculosis exists without containing tubercle bacilli. There were, of course, many other ways in which the dairy, as ordinarily conducted, might become infected. Chief among these means was through the agency of dogs, cats, rats, and mice, which are allowed to run at will about the dairy. Similarly, slaughter houses are quite commonly important centres of infection In considering how best to stamp out bovine tuberculosis, it should be borne in mind that in the early stages of tuberculosis the disease can be detected only with the aid of tuberculin. Tuberculin reveals all stages of the disease, from the earliest and almost insignificant changes to the gravest lesions of the advanced stages, and ordinarily this test does not discriminate between these classes of cases. Moreover, tuberculin is not infallible, for in a small percentage of cases it fails to reveal the disease, and occasionally a sound animal gives the reaction of tuberculosis. In spite of these drawbacks tuberculin has become indispensable to the owner of cattle. In conclusion, Dr. Grout said that such legislation was needed as would require the tuberculin test to be applied to every bovine animal in the State, and the slaughter of every animal responding to the test; also the immediate cremation, or when this was impracticable, the thorough burying of the carcasses.

Dr. F. A. Rich, of Burlington, in discussing the paper, said that glanders was not very common in Vermont, and when it did occur its true nature was often not recognized. He called attention to the fact that where there are no cows, man is not afflicted with tuberculosis.

Dr. C. W. Peck, of Brandon, reminded his hearers that five thousand people were dying from tuberculosis every year in the State of Vermont, and that six thousand children under six years of age succumb annually to the effects of bad milk.

Milk Supplies.—Edgar B. Moore, Esq., of Rutland, read a paper on this subject, in which he described the unhygienic conditions found in many dairies. His remedy was "agitate and educate."

Dr. P. P. White, of Williamsville, advised all farmers to have their cows tested with tuberculin before offering the milk for sale, and explained how they would be benefited by so doing.

Drs. G. G. Harshall, of Wallingford, and W. H Vincent, of Orwell, also spoke in the same strain

Smallpox Eruptions.—Dr. J. H. McCollum, Superintendent of the South Department of the Boston City Hospital, delivered an address on this subject, which was freely illustrated with lantern slides. He said that mild cases of smallpox in an early stage were very difficult to diagnose, but this very liability to error made these cases peculiarly dangerous to the public health. The great value of vaccination as a protection was emphasized by the citation of illustrative cases. He said that he had yet to see a person die of smallpox who had been successfully vaccinated within three or four years of the attack. The speaker said that the conditions existing at the present time in this country were so similar to

those which had preceded the smallpox scourge of 1871-72 that he was inclined to believe that the country was now on the eve of an epidemic of smallpox.

Plumbing.—William P. Gerhard, C. E., of New York City, was the author of this paper. He said that the danger from sewer gas had been greatly exaggerated, and while it could not be definitively stated that diphtheria, typhoid fever, and similar diseases actually originate in this way, it was known that exposure to the emanations from sewers weakens the system and renders the individual more susceptible to disease invasion. Great advances had been made in plumbing, but the modern system had become so complicated that there was need for a simpler and less costly, though effective plan.

Vital Statistics.—Dr. Cressy L. Wilbur, Superintendent of Vital Statistics for Michigan, read this paper. He said that the importance of such statistics was not sufficiently appreciated, yet their study was the study of the condition and growth of the race, and they were most valuable guides to health officers in their work and in securing sanitary legislation. Vermont had been one of the first ten states to adopt measures for the satisfactory compilation of vital statistics, but she had not yet sufficiently provided for their publication and distribution. There was now a movement on foot toward securing uniformity in these statistics, and Vermont and Michigan had taken the lead in this matter.

Value of a Blood Examination.—Dr. B. H. Stone, Bacteriologist of the Laboratory at Burlington, discussed the advances made in this field, and insisted upon the great diagnostic aid rendered by such examinations.

The Value of the Vermont State Laboratory to the People.—Dr. M. J. Wiltse, of Burlington, presented a paper, in which he showed by numerous letters the high character of the scientific work done in this laboratory, its value in medicolegal investigations, and the great financial saving it had effected for the State.

Dr. S. E. Maynard, of Burlington, said that when the Widal reaction was obtained with a dilution of one to nineteen he considered that a positive diagnosis of typhoid fever was warranted. In cases of poisoning by mercury or arsenic, or in cases of malaria the diagnosis should be made by an examination of the blood.

Dr. John Gibson, of Vergennes, said that it was often difficult for the medical practitioner to convince a family that one of their number was sick with typhoid fever if the symptoms were mild, hence it was frequently impossible to secure proper nursing for the sick one; however, all this disappeared if the family physician were able to back up his diagnosis by a report from the State Laboratory.

Hon. F. D. Proctor, of Proctor, declared that the State Laboratory was emphatically the people's institution, and he believed no appropriation made by the Legislature more worthy than the one for the State Laboratory of Hygiene and no board more worthy of public confidence and support than the State Board of Health. The water analyses made at the laboratory had led to the abandonment of many old wells and questionable water supplies, and the good results of such improved sanitation were far-reaching and well-nigh incalculable.

Dr. Fred Fletcher, of Bradford, gave it as his opinion that the expense of maintaining this laboratory had been more than met by the saving of health and life effected simply by the water analyses.

Drinking Water and Disease.—Professor W. T. Sedgwick, of the Massachusetts Institute of Technology, read a paper on this subject, and exhibited a series of lantern views. He said that that first great epidemic successfully traced to drinking water in modern times had been an epidemic of Asiatic cholera in 1854, but water had been known to be the bearer of disease for a much longer period. The Romans had been aware that lead might be in drinking water, and while at the present time our people are well aware of this danger another public agitation of the subject was desirable, as the poisoning of water by lead pipes was again becoming unpleasantly frequent. Several illustrative cases were narrated.

Mr. C. P. Moat, of Burlington, said that out of forty-two analyses of water made at the State Laboratory since January the water had been condemned in twenty-nine, and had been adjudged suspicious in eleven, instances, yet there were many other water supplies in constant use that were no better. In one instance a family, in which there was typhoid fever, sent a specimen of the drinking water for analysis with the comment that the dark color of the water was probably owing to the heavy rains having soaked down through the stable manure which covered the well.

Disposal of Sewage.—Professor Sedgwick also read a paper on this topic. He said that by sewage was meant the waste matters of human and animal life. That it could be disposed of on land without creating disease was shown by the fact that hospitals and children's asylums are located on the sewage fields of Berlin. Chemically, sewage is composed of a good deal of salt mixed with free and albuminoid ammonia and a vast number of microbes. Most of these microbes act as purifiers of the sewage, but as a few may be pathogenic our aim must be to destroy them all. He recommended that farmers do away with cess-pools, and instead use a piece of sandy land, or land upon which loads of sand had been dumped, for the purification of the sewage.

School House Sanitation.—Dr. W. L. Hoisington, of Weathersfield, read a paper on this subject, which was discussed by several of those present.

New Instruments.

THE DE GARMO NEEDLE FOR HERNIA OPERATIONS.

By W. B. De Garmo, M.D.,
New York.

In the issue of this journal of May 4, Dr. Campbell Ford, of San Francisco, writes on the "Radical Cure of Hernia," and has kindly mentioned my name in connection with a blunt needle which has been used by me in performing the Bassini operation. His sentence, "I do not know where the needles may be had, but no doubt a letter addressed to Dr. De Garmo would obtain that information," has convinced me on two points, viz., 1. That the circulation of the Medical Record is large; 2. That interest in hernia continues, notwithstanding the voluminous literature upon the subject. These facts have been borne in upon me by the large number of inquiries received from physicians and instrument-makers about the very simple little needle which I have hardly deemed worthy of publication, as there is certainly nothing very original about it.

After many hundred trials it has, however, proven itself to me more useful than any other needle of which I have knowledge for carrying out the Bassini method, and it adds one element of safety to the operation. The accompanying illustration shows it at its actual size. It is merely a strong, round needle of full curve, blunt point, and without cutting surface. It will appear to many as too small for convenient use, but it has been found that one of larger curve cannot be easily turned at the bottom of a deep canal. A little practice will enable one to use it without a needle-holder. Its eye is large, to allow of the quick threading of even quite large strands of kangaroo tendon.

The objects attained by using a needle of this character are: 1. Safety. Several instances are known of the perforation of deep and large vessels by a sharp

needle with cutting point, and consequent severe bleeding. The writer knows of one death which was undoubtedly the result of this accident. 2. The round, blunt needle in passing through muscular and aponeurotic structures separates their fibers, instead of cutting them, and it is believed that in this operation no muscular tissue should be cut.

The needle is used for closing the two deep layers.

56 West Thirty-sixth Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 27, 1901:

	Cases.	Deaths.
Measles	120	10
Diphtheria	122	16
Laryngeal Diphtheria (Croup)		
Scarlet fever	114	16
Smallpox	46	9
Chickenpox	8	
Tuberculosis	255	153
Typhoid fever	37	13
Cerebro-spinal meningitis		8

Impressions of a German Congress.—An occasional correspondent of the *British Medical Journal*, who speaks from experience, has been moved to unburden his soul as to the mode in which discussions are carried on at some German scientific congresses. The picture he draws is not, he declares, exaggerated, but his remarks must be understood as applying only to the congresses which are not divided into sections, and in which the discussions take place in plenary session. "There is a large room where the congress is to take place, filled with hundreds of our colleagues, of German and other nationalities. These gentlemen are prepared for several days' ennui, but are also resolved not to let it be all dull. They present a very varied appearance, and produce a very varied impression by the complexity of sound, which their conversation before the commencement of the proceedings creates. The management consists of a chairman, who is changed at each sitting, and his confrères, the president, the secretary and the other members of the council. The chairman opens the day's proceedings by informing the readers that the time limit, namely, half an hour for papers and ten minutes for discussion, will be rigidly adhered to. At first all goes smoothly, until a speaker has occupied the attention of the house for twenty minutes or so, when there is heard an ever-increasing buzz of conversation from the back part of the room. Of this the speaker takes no heed, and when the half hour is past, the chairman merely stretches himself and remains quiet. The next speaker has obviously not been fortunate in the impression that he has made on the house, for the conversation, begun during the last speech, continues and becomes disturbing. But he, being accustomed to such trivial inconveniences, labors on steadily. The hands of the clock steal slowly onward, and when they register that the speaker has been standing at the desk for nearly twenty minutes, a single cry of 'End' (Schluss) is heard. Soon the air is rent with wild, delighted cries of 'End,' and feebly tempered by a few remonstrating 'Gsch.' The chairman rings his bell. Some order is restored, and he tells the speaker that he has two minutes more. Poor speaker! He has lost the thread of his argument (for papers must be given from memory, not read); he is face to face with the fact that he has but two minutes more to live—as a speaker—and he thereupon precipitates himself headlong into his subject, at such an enormous rate, and with so much energy, that it becomes a matter of impossibility to understand what he is speaking of. The noise at the far end of the room continues, and in one minute the second sound of the bell is heard. The chairman now shows his humanity, and asks the house to decide whether the speaker shall continue or not. This is done either by direct appeal, an interpretation of the responsive sound as to what the wish of the majority is, or by a show of hands. There is a subtlety in the decision, for, if the chairman wishes, he can rule on a single show, or he may ask for ayes and noes, or he may compare the number of hands shown with the number of persons present. But it is decreed that our friend the speaker must stand down, and there is something pathetic in his self-conscious, proud and satisfied bow, and the deathlike silence which follows it for one moment. A discussion now takes place. At first absolute oblivion of time seems to surround the chair, and the first intimation which the occupant of it receives of the fact that one member has occupied the platform for nearly half an hour is that his conversation with a colleague is interfered with by a dozen eager members, who wish to have their say. Then he rings the bell, and asks if the speaker has much more to say, but to do this he waits until the latter has reached the middle of a sentence. 'I am just finished', is the reply; five minutes later, a further ring, the same question, the same reply. Still five minutes later the chairman says that Herr X. is in possession of the platform, and requests the loquacious one to stand down. He forgets to bow, and, collecting his notes and papers slowly, mumbles that he has had no time to give his most important points of argument."

The Bacterial Treatment of Constipation.—Some recent researches of Roos, of Freiburg, into the bacterial treatment of constipation deserve careful attention. He found that cultures of bacillus coli communis, derived from persons whose bowels were active, effected a cure when administered to persons suffering from constipation. His experiments were carried out upon himself and upon some half-dozen medical friends. Accepting the facts as stated, it follows that there is a difference in the activity and vital reaction of various members of the bacillus coli group. That many varieties exist in that particular family has long been an established fact. In connection with this subject, it may be pointed out that some observers have described a form of diarrhœa associated with bacillus coli. Again, the origin of more or less summer diarrhœa has been attributed to the pollution of town dust by the bowel bacteria of the horse. It would be not a little interesting to learn whether Roos has conducted his researches into the relation of the equine bacillus coli to the constipation of man. In any case he has opened up a most interesting and suggestive line of observation, and one that promises to yield practical results in the direction of treatment. The subject of the bacteriology of the intestine, both in health and in disease, is enormously wide and important, and offers a fine field of investigation to the rising generation of bacteriologists.—*Medical Press and Circular.*

The Toxicology of Carbolic Acid.—At an enquiry recently held, says the *Medical Press*, into the circumstances attending the death of several sailors, consequent upon the bursting of some barrels of crude carbolic acid, certain curious facts came to light, bearing on the toxic powers of this acid. The men were deputed to make fast the rolling casks, and in so doing they were severely burned, though not to such an extent as to account for death, which took place with startling suddenness. According to Dr. Dupré, the immediate cause of death was absorption of the acid through the skin, this crude acid not burning the skin like the pure acid. If this be so, the absorptive powers of the skin in respect of carbolic acid must be vastly greater than towards most other substances. We do not gather that there was any post-mortem evidence in support of this hypothesis, and, in view of the fact that this distinguished chemist stated that he had kept a

mouse saturated with the acid for half an hour without the slightest effect the suggestion appears rather risque. Considering that the hold in which these men were working was two feet deep in the acid, it is matter for surprise that any of them should have escaped with their lives; but it is important from many points of view that the exact cause of death should be made clear, and a study of the evidence given at the inquest does not enable us to decide this question.

A Clever Thief.—The Paris correspondent of the *Lancet* relates that a specialist in mental diseases was recently consulted by a man of distinguished appearance, giving an aristocratic name, who sought treatment for a daughter suffering from kleptomania. Suggestive therapeutics was instituted, and little attention was paid to the propensity for misappropriation exhibited by the patient, particularly as the abstracted articles were returned the day after their removal. Finally the physician missed a jewel box of value, but this was not brought back, and, on investigation, it was found that the address given was false, and that the pretended patient and her father were most crafty rogues.

Insects and the X-Rays.—A box was made half of wood and half of sheet lead. In the wooden half a number of larvæ of flies, bees, beetles, and other insects was placed, and the box was then put in the field of the *x*-rays. The insect colony at once became greatly excited, and after crawling to and fro, finally emigrated, to a worm, to the leaden half of the box, where the rays could not penetrate. The experiment was repeated many times, and always with the same result. A similar experiment was tried with the blind larvæ of a certain species of beetle. A number of them were placed in an open cigar box, which also contained a metal box with an opening. No sooner were the rays turned on than the insects showed signs of distress. Their uneasiness increased, and in a little while they all sought refuge in the metal box. As the larvæ in the second experiment were entirely sightless, their perception of the rays must take place through the nerves of the skin.—*The American X-Ray Journal.*

An Alleged Marriage Law in Pennsylvania.—According to a Parisian medical contemporary, the marriageable maidens in Pennsylvania have been the object of a special solicitude on the part of the Solons of the State Legislature. This journal says that a Pennsylvania law for the encouragement of marriage provides that any male citizen more than forty years of age who wishes to remain single must apply for a dispensation from marriage and pay therefor the sum of $100. The money so obtained is to be applied to the maintenance of homes for old maids who have received no offers of marriage or none of an acceptable character. This seems to us an unfair discrimination against the men, who must marry willy-nilly, while the women have the right of choice. But the legislature went further, not only favoring the women over the men, but even laying an impost duty on foreign brides, regardless of the unconstitutionality of interstate imposts. The same journal states that every male Pennsylvanian, forty years or more of age, who marries a woman residing outside of the State must pay a fine of $100 for the insult thus offered to the virgins of his own commonwealth.

Did Napoleon Die of Cancer?—The belief is very general that the cause of death of the great Napoleon was cancer, and it is generally believed that cancer was in the family. Dr. Baudouin has lately published, in the *Gazette médicale de Paris*, some clinical remarks on the death of Napoleon I., and the conclusion he arrives at, apparently on perfectly reasonable grounds, is that the great Emperor suffered from an ulcer of the stomach, which caused death by perforation. Undoubtedly, hæmatemesis was present as a symptom, and at the autopsy there was no hypertrophy of the liver, nor any sign of cancer, but a gastric ulcer which had perforated was found near the pylorus. The whole controversy exemplifies very clearly the extreme difficulty of correcting a mistake of this kind. It will be remembered that Napoleon's last illness was of about four years' duration, and this time would fit in with the diagnosis of cancer, though it is undoubtedly true that a competent authority diagnosed chronic hepatic disease, and later abscess of the liver; but Dr. Baudouin believes this to have been a perihepatitis due to extension from the existing ulcer of the stomach.—*Medical Press and Circular.*

Nervous Diarrhœa.—Pariser distinguishes five forms of nervous diarrhœa, due to (1) central nervous influences; (2) toxic causes, as from tæniæ, nicotine, morphina; (3) reflexes from the pelvic organs, stomach, nose, or skin; (4) neurasthenia; (5) combined catarrh and neurosis. The differential diagnosis is easy when the primary cause is pronounced, especially when the symptoms point to neurasthenia, while one of the most valuable signs is presented in persistence of the diarrhœa after adoption of a simple non-irritating dietary. The great abdominal nervous plexuses are often hyperæsthetic; mucus is absent from the stools, save sometimes in the fifth group; other objective signs are lacking. The treatment resolves itself into finding first, the cause, then removing it.—*Edinburgh Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General United States Marine-Hospital Service, during the week ended July 27, 1901:

		CASES	DEATHS.
SMALLPOX—UNITED STATES AND INSULAR.*			
Alaska, Juneau	July 3d	1	
California, Los Angeles	July 6th to 13th	1	
San Francisco	July 7th to 14th	1	
Illinois, Chicago	July 13th to 20th	1	
Louisiana, New Orleans	July 13th to 20th	1

THE PROPAGATION OF YELLOW FEVER: OBSERVATIONS BASED ON RECENT RESEARCHES.*

By WALTER REED, M.D.,

SURGEON U. S. ARMY.

MR. PRESIDENT AND GENTLEMEN OF THE FACULTY: If, upon receipt of your kind invitation to be present with you to-night my first impulse was to decline, I beg that you will not attribute this to any want of appreciation on my part of the honor conferred, but solely to my desire to avoid what I felt would be a very embarrassing position, should I attempt to follow in the footsteps of the distinguished gentlemen whom you have invited to fill this position from year to year. Recognizing in them, as all willingly do, leaders in the profession, who, by their well-considered addresses, have been able to add so much to the scientific interest of your annual meetings, I could but feel that the burden which you proposed to put upon me was greater than I could bear. That, nevertheless, I am here, in the capacity of your annual speaker is due to my unwillingness even to appear disobliging to this old and honorable association of physicians, amongst whose number I find included some of my most valued friends; friends who, in years gone by, have labored so faithfully to instill into my mind the value of the scientific method, but to whom I have been able to make such small return. If, therefore, I drew some encouragement from the feeling that I should not be wholly among strangers, I found yet more in the thought that such an eminent body of physicians as this Faculty must ever be willing to welcome any contribution that promises to shed light upon a subject hitherto enshrouded in darkness, and which thereby holds out the prospect of an addition to our knowledge in the larger field of preventive medicine.

In the hope that what I have to say to-night may contribute to the solution of a somewhat obscure problem, and may assist us hereafter in the struggle with a grave epidemic disease, I have concluded to present for your consideration "The Propagation of Yellow Fever, Based on Recent Researches."

Before proceeding to the discussion of this subject, it is fitting that I should pay brief tribute to the memory of a former member of this Faculty, the late Dr. Jesse W. Lazear, United States Army. I can hardly trust myself to speak of my late colleague, since the mention of his name brings back such scenes of anxiety and depression as one recalls only with pain. Along with these sad memories, however, come other recollections of a manly and fearless devotion to duty such as I have never seen equaled. In the discharge of the latter, Dr. Lazear seemed absolutely tireless and quite oblivious of self. Filled with an earnest enthusiasm for the advancement of his profession and for the cause of science, he let no opportunity pass unimproved. Although the evening might find him discouraged over the difficult problem at hand, with the morning's return he again took up the task full of eagerness and hope. During a service of less than one year in Cuba, he won the good-will and respect of his brother officers, and the affection of his immediate associates. Almost at the beginning of what promised to be a life full of usefulness and good works he was suddenly stricken, and, dying, added one more name to that imperishable roll of honor to which none others belong than martyrs to the cause of humanity.

It is my own earnest wish that, whatever credit may be hereafter given to the work of the American Commission in Cuba during the past year, the name of my late colleague, Dr. Lazear, may be always associated therewith.

I do not propose to set before you this evening so much the views of others in relation to the etiology of yellow fever or to the conditions under which it originates and spreads, as to give you the results of my own experience with regard to the manner in which this disease propagates itself. In the ordinary course of army administration, I found myself brought in contact with yellow fever during the summer of 1900, under such circumstances as permitted me to give my entire time to the study of its etiology and propagation. Permit me here to remark that so many claims have been made as to the specific cause of yellow fever—claims that could not be confirmed by other investigators—that one must needs feel considerable hesitancy in considering this remarkable disease from any aspect. I must confess that I have experienced, in the highest degree, this feeling of reluctance to write or speak about yellow fever, especially when I recall the frame of mind of myself and my colleagues—that of utter perplexity and wonder—as we stood by the bedside of patients, or at the autopsy table of those who had died of this mysterious malady. I trust, therefore, that whatever I may say here to-night will be considered as a modest expression of opinion growing out of an unprejudiced study of yellow fever, for the most part from the point of view of its propagation.

Although considerable attention had been given to the laboratory study of the microorganisms isolated by Sternberg and Sanarelli from the organs of yellow fever cadavers, this did not enable one to form any opinion concerning the nature of the disease or the mode of its propagation.

At the time of our arrival in Cuba—June, 1900—the situation as regards the etiology of yellow fever may be briefly stated as follows: The claims of all investigators for the discovery of the specific agent of this disease had been disproved by the exhaustive work of Sternberg,[1] published in 1890, except that made by Dr. Sanarelli, in June, 1897, for his *bacillus icteroides*. I need not take up time here with mention of those who had investigated Sanarelli's claim, except to state that the confirmation of his discovery came chiefly from workers in the United States, of whom I may speak of

*Address delivered at the One Hundred and Third Annual Meeting of the Medical and Chirurgical Faculty of the State of Maryland, held at Baltimore, April 24–27, 1901.

[1] Report on the Etiology and Prevention of Yellow Fever, 1890.

Achinard and Woodson, of New Orleans, and especially of Wasdin and Geddings of the Marine Hospital Service. The latter in a report,[2] submitted during the summer of 1899, accepted in the fullest Sanarelli's claim for the specific character of *bacillus icteroides*, basing their confirmation on the finding of this bacillus in thirteen out of fourteen cases of yellow fever studied by them in the city of Havana. Under these circumstances, it was of the first importance that we should give our entire time to the search for *bacillus icteroides* in the bodies of yellow fever cases. The result of this study, embracing twenty-one cases during life and eleven autopsies, and which was entirely negative, has already been given in our Preliminary Note,[3] read at the last meeting of the American Public Health Association (1900).

Turning for a moment to our knowledge concerning the mode of propagation of yellow fever, the situation, when we began work, was about as follows: The battle for or against its importation having been already decided in favor of the former belief, its transmissibility from place to place was attributed to the individual affected by the disease, but especially to his clothing; with the proviso, however, that intimately connected with its spread was involved a proper constitution of the atmosphere of the place, this latter due chiefly to insanitary conditions of soil. That the excreta of the patient contained the specific agent of the disease was supported by many good authorities. That the disease could be propagated by fomites was not disputed by any one. Against its spread by the sick and by fomites all quarantine measures were being then directed.

The theory of Finlay for the propagation of yellow fever by the mosquito, concerning which I shall presently have something to say, had either gained no credence, or been rejected by reason of the absence of any results that had been presented by its author in support of it. In the meantime, and before we had completed our search for Sanarelli's bacillus, certain facts had been cropping out, as it were, which served to arrest the attention. Just here, while mentioning the first fact, let me say that one does not like to confess his ignorance of such a well-known disease as yellow fever, especially before an audience some of whose members may have already treated cases during the last epidemic in this city, in the year 1876; and yet candor compels me to record my very great surprise, when brought face to face with yellow fever, to learn that attendance on patients by non-immune nurses, in every stage of the malady, involved no danger. In other words, that yellow fever, both in the wards at Columbia Barracks, as well as in the wards of Las Animas Hospital, Havana, was not contracted by the attendants under circumstances such as those in which typhoid fever and Asiatic cholera are too often conveyed. Further inquiry along this line seemed to indicate that the disease had not been contracted in hospitals, even during the earlier epidemics, when disinfection of articles of clothing and bedding was unknown.

A second fact which appeared worthy of note, was the discharge of patients from the wards during early convalescence, and their return to the companionship of their comrades with apparently no danger of establishing fresh foci of the disease. This hardly seemed in keeping with the presence of a specific agent in the excreta of the sick.

A third fact which stood out prominently was that, in certain of our cases, no growth whatever was obtained on our present laboratory media, either by frequent cultures taken from the blood during life or from the organs after death. In other words, no bacterium was obtainable by aerobic methods, in certain of our cases, either during life or after death. This result had considerable weight in controlling our future work.

During the time that these cases were being studied, opportuntiy was afforded to investigate an epidemic of fever which was prevailing in Pinar del Rio Barracks, near the town of this name, distant one hundred and ten miles from Havana, and of which fever several soldiers, in a garrison of about nine hundred men, had already died. A visit was made to this garrison with my colleague, Dr. Agramonte, on the 31st day of July, 1900, and a body sectioned the same afternoon. The lesions found were those of yellow fever. Inquiry showed that under the diagnosis of "remittent malarial fever" or "pernicious malarial fever," the disease had been prevailing for at least thirty-seven days prior to our arrival—July 21—and that about thirty-five cases had been under treatment in the Post Hospital, of which number eleven had died. As the true nature of the disease had not been suspected, no precautionary measures had been taken as regards the disinfection of bedding and clothing used by the patients, except that in case of death, the sheets and pillow slips were put in bichloride solution and the mattress and pillow exposed to sunlight. An order required that the excreta of all patients under treatment in this hospital should be carefully disinfected, and this was probably carried out fairly well. The excreta for the garrison at large were incinerated in permanent crematories, fires being lighted in these twice a week.

Notwithstanding the omission to disinfect the bulk of the contaminated articles of bedding and clothing, the disease had not been contracted by the nurses, nor by the other patients in the several wards, nor by the three men who washed all of these articles. A little inquiry showed that contaminated clothing was in all of the eight barrack-rooms without apparent detriment to the occupants. Further investigation showed that a death from yellow fever had occurred in this garrison as early as May 16, 1900, and that the source of infection for this case, as well as for the present outbreak, was in the immediately adjacent town of Pinar del Rio, to which the soldiers had free access.

An interesting observation was the sudden attack of yellow fever experienced on July 12, 1900, by a general prisoner who had been confined in a cell in the guard house since June 6, 1900. His death occurred at the Post Hospital on July 18, 1900. This cell was occupied, at the time, by eight other prisoners, none of whom contracted the disease, although one of them continued to occupy the bunk vacated by the sick man. As these nine prisoners had been kept under strict military guard, it was impossible that the individual attacked could have acquired his infection in the town of Pinar del Rio. He was, as far as could be ascertained, exposed to no source of infection to which his companions had not been equally exposed, and yet he alone acquired the disease. It was conjectured at the time that, perhaps, some insect capable of conveying the infection, such as the mosquito, had entered through the cell window, bitten this particular prisoner and then passed out. This was, however, only a supposition.

Two instances of undoubted exposure to fomites, involving four individuals, came under my observation during this inspection. In the one case a box of clothing, belonging to a soldier who had died

[2] The Cause of Yellow Fever. Washington, 1899.

[3] The Etiology of Yellow Fever, A Preliminary Note. *Phil. Med. Journal*, Oct. 27, 1900.

of yellow fever on July 3, and which had been packed by an enlisted man on July 4, and placed in the company store-room, was unpacked for the purpose of making an inventory of the articles, and carefully repacked on July 18, by two non-immune soldiers, who did not contract the disease by this exposure. In the other case, the very bed vacated on July 18 by the Commissary Sergeant, who was taken sick on July 17, and died on July 21, was occupied by a non-immune soldier on the night of the 19th and 20th of July. Although this individual was badly frightened when the true character of the Sergeant's attack was announced, the combination of fright and exposure to fomites was not sufficient to produce an attack of yellow fever.

The data gathered, therefore, during the investigation of this small epidemic at Pinar del Rio, did not tend to strengthen one's belief in the theory of the propagation of yellow fever by fomites. This belief had already been shaken by the manner in which the disease had spread in the town of Quemados, Cuba, from which we had obtained cases for bacteriologic study; for here we saw the disease pass from No. 102 Real street around the corner to No. 20 General Lee street, and thence to a house immediately across this latter street, without the passage of any persons between these three houses, and to the exclusion of any article of clothing, as the three families had no acquaintance whatever with each other. Here the infection was just as plainly carried through the air as it had been taken, through this medium, to the prisoner in the cell at Pinar del Rio. We also observed in this town that the contagion passed down General Lee street with a bound to the distance of a square, passing in its journey a house containing two non-immunes, only to return, a few days later, to this very house and seize upon both of its non-immune inmates. This hardly seemed in keeping with the idea of a diffusible poison carried by the atmosphere. During our first week on the island, we noted in a house in Quemados, where the husband and wife were taken down with yellow fever, a few days apart, that neither the young daughter, who was removed to a place of safety on the fourth day, nor an attendant who had remained in the sick room for the entire tweny-four hours of the seventh day, had acquired the disease; but that of the two remaining nurses who continued to perform their duties, one was seized on the fourteenth day and the other on the fifteenth day, with an attack of yellow fever. This observation was recorded at the time for what it was worth. Later it was found to harmonize with the observations which had been made by Surgeon Henry R. Carter, of the Marine Hospital Service, in 1898. As I shall recur to these observations later in my remarks, it will suffice to here state that, at this stage of our investigation it seemed to me, and I so expressed the opinion to my colleagues, that the time had arrived when the plan of our work should be radically changed; that the search for the specific agent of yellow fever, while not abandoned, should be given secondary consideration, until we had first definitely learned something about the way or ways in which the disease was propagated from the sick to the well. I felt well-nigh convinced that we could obtain no light whatever upon the task that had been set before us, unless we substituted this line of work for the one we had been pursuing, and that in view of the splendid work of Ross, Bignami and others with regard to the propagation of malarial fever, together with the well-known thermal influences intimately connected not only with the epidemiology of the disease in the United States, but also with its endemiology on the Island of Cuba, it was of the highest importance that the agency of an intermediate host, such as the mosquito, should either be proven or disproven.

Remember, if you please, that here we were dealing with an epidemic disease, concerning which there was no evidence whatever to show that it had ever been spread by contamination of either water or food; that it had always demanded a certain elevated temperature before it would begin its progress, which latter both in its manner and rate was quite unlike that of other epidemic diseases, such as smallpox or typhoid fever or Asiatic cholera: that once having begun its march, no hygienic measures ever instituted had been able to arrest its course, except depopulation of the locality affected; that while if introduced into certain localities, it would readily propagate itself, those sick with this disease could be carried in large numbers into other places without any danger of its spread—a fact which had been attested in hundreds of instances; that ships with non-immune crews could remain at anchor, with perfect safety, at about three hundred yards from an infected shore; couple with this the natural law by which it was governed, viz., its prompt control by frost, and tell me what other epidemic disease could be associated in the mind with this except malarial fever?

The theory that the spread of yellow fever could not be explained by the assumption of a diffusible miasm in the atmosphere, but required the presence of an intermediate host, appears to have been first advanced by Dr. J. C. Nott, of Mobile, Ala., in March, 1848. His views were given in full in the *New Orleans Medical Journal* for that year. It was also in this paper that Nott suggested the mosquito as the possible agent in the dissemination of malarial fevers. He evidently did not have in mind the mosquito as the bearer of the yellow fever poison, but rather that this important office was performed by some insect or insects that remained very close to the ground. Referring to the fact to which all writers were agreed that a very imperfect barrier, such as a row of houses or of trees, would often protect dwellings from the access of malarial poison, he says: "I have been able in my researches to discover no facts of this kind in connection with yellow fever, and my personal observation repudiates this *in toto*. We never find yellow fever, as the sportsman says, "up a tree" but on the contrary, the *materies morbi*, whatever it may be, creeps along the ground, regardless of winds, passing under and through houses and trees, etc., and knowing no impediment but a sheet of water." Again, "It is a curious fact that from 1829 to 1837 there was no epidemic of yellow fever in Mobile, and during this time the streets were beautifully shelled; since 1837 we have had it five times, and the shelling was not continued. If the insect theory be correct, could the lime be an impediment to their progress across the street?"

To Dr. Carlos J. Finlay, of Havana, must be given, however, full credit for the theory of the propagation of yellow fever by means of the mosquito, which he proposed in a paper read before the Royal Academy in that city at its session on the 14th day of August, 1881. From that date to the present time, Finlay has made a number of valuable contributions to the origin and mode of transmission and the prevention of yellow fever. During this time his views have undergone some slight modification. Starting with the idea that the specific poison adhered to the mosquito's proboscis and was thus mechanically transferred to the individual next bitten (which specific agent was claimed by him in 1887, and even at the present time, to be his *micrococcus tetragenus febris flavae*), he later—1899—modified his original theory, based

upon the studies of Theobald Smith on Texas fever, "so as to include the important circumstances that the faculty of transmitting the yellow fever germ need not be limited to the parent insect, directly contaminated by stinging a yellow fever patient (or perhaps by contact with or feeding from his discharges), but may be likewise inherited by the next generation of mosquitoes issued from the contaminated parent" (NEW YORK MEDICAL RECORD, May 27, 1900). Of the one hundred individuals experimented upon from June, 1881, to May, 1895, Finlay claimed to have produced three cases of "mild albuminuric fever," after a period of incubation varying from five to twenty-five days; but as he exercised no control over these individuals, to the exclusion of other sources of infection, no value could be attached to his results. If, indeed, one were guided by the results obtained, the only logical conclusion to be drawn was that Finlay had disproved his own theory. His failure to produce positive results—which we now believe to be due to the fact that he did not keep his insects for a sufficient length of time after contamination, before applying them to the individual to be infected—doubtless led Finlay to promulgate the later idea that the bite of the contaminated mosquito, while not producing the disease, conferred immunity upon the individual bitten. He has made use of the bite of the contaminated mosquito for this purpose in a considerable number of individuals. Notwithstanding the fact that Finlay had no results to show in support of his theory, and that the latter had been wholly rejected by other investigators, the argument in favor of an intermediate host seemed so strong, as I have already stated, that further investigation along this line was determined upon. The mosquito selected was the one that had been used by Finlay in his previous work, and which with *Culex pungens*, is the most prevalent and annoying mosquito in the city of Havana, and for that matter in all the larger towns on the Island. Originally designated by Fabricius as *Culex fasciatus*,* it had later been called by Desvoidy, *Culex mosquito*. Unlike *Culex pungens* this mosquito bites by day as well as during the night time. Judging from my own experience, I should say that its favorite hours for feeding were from 4 P. M. to 10 P. M.

In our preliminary note above referred to, we recorded amongst eleven individuals bitten by contaminated mosquitoes of this species, nine negative and two positive results; the attack in both of the latter occurring within the period of incubation of yellow fever. As the circumstances surrounding the infection of one of these cases was such as to exclude any other source of infection, we announced the conclusion that "the mosquito served as the intermediate host for the parasite of yellow fever." Subsequent observations have pointed, in the most convincing manner, to the soundness of this conclusion. It is to these later observations that I now desire to invite your attention.

Dismiss from your minds, if you please, the idea that yellow fever is so prevalent on the Island of Cuba and that the ways of acquiring the disease so numerous, that experimental results obtained at any point in the so-called endemic Zone of Yellow Fever must be thereby vitiated. Nothing to my mind could be more improbable than such an opinion; for as a matter of fact yellow fever has been confined, during the year 1900, to Havana and a few other towns, coast or inland, and has not been present elsewhere on the Island. Hence any location selected, provided it should be one mile from such a center of infection and surrounded by proper safeguards, would be just as free from the occurrence of yellow fever as if it were located ten miles from such a town. My own experience on the Island of Cuba had already taught me that yellow fever could be easily kept out of a military garrison, although prevailing in epidemic form in a town less than one mile distant. For this reason it was not considered advisable to establish our Experimental Sanitary Station at a greater distance than one mile from Quemados, Cuba. Thus Camp Lazear could be easily reached by the members of the Board and was conveniently located as regards its base of supplies. The occurrences at this camp fully justified this decision. Placed in an open field, which was fairly swept at all times by the prevalent winds, and having a military garrison each of whose members had been personally selected by reason of former good conduct and interest in the work to be here undertaken, no difficulty whatever was experienced in maintaining the strictest quarantine against the outside.

Let us now present to you, as succinctly as possible, our observations at this camp, prefacing what I shall have to say with the remark that here we proposed to attempt the infection of non-immune individuals in three ways, viz., first, by the bites of mosquitoes that had previously bitten cases of yellow fever; secondly, by the injection of blood taken during the early stages from the general circulation of those suffering with the disease, and, thirdly, by exposure to the most intimate contact with fomites. For this purpose, in addition to the seven tents provided for the quartering of the detachment, two frame buildings, each 14x20 feet in size, were constructed. These buildings, having a cubic capacity of 2,800 feet, were exactly similar, except that one of them, known as the "Infected Mosquito Building," was divided near its middle by a permanent wire screen partition and had good ventilation; while the other, designated as the "Infected Clothing Building," was purposely so constructed as to exclude anything like efficient ventilation. These houses were placed on opposite sides of a small valley, about eighty yards apart, and each seventy-five yards distant from the camp proper. Both houses were provided with wire screen windows and double wire screen doors, so that mosquitos could be kept without or within the buildings, as the experimenter might desire.

At first the results obtained at this station were not encouraging. From November 20, 1900, the date of the establishment of the station, until December 4—a period of two weeks—we had tried to infect four individuals with entirely negative results. Two of these had been bitten twice, at intervals of three days, by contaminated mosquitoes which had been kept from ten to fourteen days after they had fed on yellow fever cases; while the other two non-immunes had been thrice bitten, at the same intervals, by mosquitoes that had bitten cases of yellow fever ten to eighteen days before. As the weather during this time was cool and the insects had been kept at room temperature (and this is practically out-door temperature in Cuba), we conjectured that the negative results might, perhaps, be thus explained. We remembered that Daniels[4] in repeating, during the winter season Ross' observations with proteosoma infection of birds, had obtained a much smaller percentage of successes than had Ross, who worked during summer weather. We would have been glad to draw some encouragement from our negative experiments, also, with infected bedding, but as at this

* It is interesting and important to observe that since the publication of our Preliminary Note, Theobold, the English Entomologist, has taken *C. fasciatus* from the genus *Culex* and placed it in a new genus—*Stegomyia*.

[4] On Transmission of Proteosoma to Birds by the Mosquito—Royal Society, Reports of Malarial Committee. London, 1900.

date (December 4) our three subjects had been sleeping with fomites only four nights (which is within the period of incubation of the disease), this comfort was debarred.

On the fifteenth day of our encampment, therefore—December 5, at 2 P.M. o'clock—we concentrated our insects, so to speak, on one of these non-immunes—Kissinger by name—selecting five of our most promising mosquitoes for the purpose. These had been contaminated as follows: two fifteen days; one nineteen days, and two twenty-one days previously. This inoculation was more successful, for at the expiration of three days and nine and one-half hours the subject, who had been under strict quarantine during fifteen days, was suddenly seized with a chill about midnight, December 8, which was the beginning of a well-marked attack of yellow fever.

I cannot let this opportunity pass without expressing my admiration of the conduct of this young Ohio soldier, who volunteered for this experiment, as he expressed it, "solely in the interest of humanity and the cause of science," and with the only proviso that he should receive no pecuniary reward. In my opinion this exhibition of moral courage has never been surpassed in the annals of the Army of the United States.

The following morning—December 9—(Sunday at 10.30 A.M. o'clock) we selected from those insects that had bitten Case I, one mosquito that seemed to us to possess the best record of contamination, as it had bitten a fatal case of yellow fever, on the second day of the disease, nineteen days before. This insect was applied to a Spanish immigrant, who had been strictly quarantined at our station for nineteen days. At the expiration of three days and eleven hours (December 9, 9.30 P.M.) this individual was also seized with an attack of yellow fever.

In the meanwhile, on December 8, 1900, at 4 o'clock P.M., we had applied to a young Spaniard three of the mosquitoes that had, three days previously, bitten Case I, together with an additional mosquito contaminated seventeen days before. At the end of four days and twenty hours (December 13, noon), this Spaniard suddenly lost his vivacity and took to his bed. The following morning, at 9 A. M., his febrile paroxysm began. His case, which was the mildest of our series, was also marked by a long period of incubation, viz., five days and seventeen hours. He had been in quarantine nine days.

December 11, at 4.30 P.M. o'clock, the identical four insects which had bitten Case III were fed on a Spanish immigrant who had been in quarantine for the past twenty-one days. At the expiration of three days and nineteen and one-half hours (December 15, noon) he was likewise seized with yellow fever.

Thus within the period of one week—December 9 to December 15—we had succeeded in producing an attack of yellow fever in each of the four individuals whom we had caused contaminated insects to bite, and in all save one of the five non-immunes whom we had originally selected for experimentation.

It can readily be imagined that the concurrence of four cases of yellow fever in our small command of twelve non-immunes, within the space of one week, while giving rise to feelings of exultation in the hearts of the experimenters, in view of the vast importance attaching to these results, might inspire quite other sentiments in the bosoms of those who had previously consented to submit themselves to the mosquito's bite. In fact several of our good-natured Spanish friends who had jokingly compared our mosquitoes to "the little flies that buzzed harmlessly about their tables," suddenly appeared to lose all interest in the progress of science, and forgetting, for the moment, even their own personal aggrandizement, incontinently severed their connection with Camp Lazear. Personally, while lamenting, to some extent, their departure, I could not but feel that in placing themselves beyond our control they were exercising the soundest judgment. In striking contrast to the want of confidence shown by these Andalusians who had agreed to be bitten by mosquitoes was the conduct now displayed by the three young Americans, who had consented to jeopardize their lives by exposure to fomites, and who, as a matter of fact, had already spent fifteen nights in a small, illy-ventilated building, breathing in an atmosphere dreadfully contaminated by the soiled garments of yellow fever patients. With the occurrence of these cases of mosquito infection, the countenance of these men, which had before borne the serious aspect of those who were bravely facing an unseen foe, suddenly took on the glad expression of "school boys let out for a holiday," and from this time their contempt for "fomites" could not find sufficient expression. Thus illustrating once more, gentlemen, the old adage that familiarity, even with fomites, may breed contempt!

As the continued good health of those who were occupying the "Infected Clothing Building" pointed strongly to the harmlessness of fomites, the next experiment at this station was undertaken for the purpose of demonstrating that the essential factor in the infection of a building with yellow fever is the presence therein of mosquitoes that have bitten cases of yellow fever.

Accordingly at 11.55 A.M., December 21, 1900, fifteen mosquitoes were freed in the larger room of the "Infected Mosquito Building," which, as I have said, was divided into two compartments by a wire-screen partition. The interval that had elapsed since the contamination of these insects was as follows: one, twenty-four days; three, twelve days; four, eight days; and seven, five days. The only articles of furniture in this building consisted of three beds, one being placed in the mosquito room and two beyond the wire screen, these latter intended to be occupied by two "control" non-immunes. The articles of bedding as well as the bedsteads had been carefully disinfected with steam. At noon on the same day, five minutes after the mosquitoes had been placed therein, a plucky Ohio boy, Moran by name, clad only in his night shirt, and fresh from a bath, entered the room containing the mosquitoes, where he lay down for a period of thirty minutes. On the opposite of the screen were the two "controls" and one other non-immune. Within two minutes from Moran's entrance, he was being bitten about the face and hands by the insects that had promptly settled down upon him. Seven in all bit him at this visit. At 4.30 P.M., the same day, he again entered and remained twenty minutes, during which time five others bit him. The following day at 4.30 P.M., he again entered and remained fifteen minutes, during which time three insects bit him, making the number fifteen that had fed at these three visits. The building was then closed, except that the two non-immune "controls" continued to occupy the beds on the non-infected side of the screen. On Christmas morning at 11 A.M., this brave lad was stricken with yellow fever, and had a sharp attack, which he bore without a murmur. The period of incubation in this case was three days and twenty-three hours, counting from his first visit, or two days and seventeen and a half hours, if reckoned from his last visit. The two "controls" who had slept each night in this house, only protected by the wire screen, but breathing the common atmosphere of the building, had remained in good health. They continued to so remain, although required to sleep here for thirteen additional nights. As Moran

had remained in strict quarantine for the period of thirty-two days, prior to his attack, the source of his infection must be found within this house.

In the order of succession the next experiment undertaken at this camp was the injection of blood, taken from Case V (Moran), beneath the skin of a Spaniard, but I will defer further mention of this line of experimentation, until I have completed the mosquito series, as these are by far the most important. I, therefore, invite your attention to Case VI, Martinez by name. His case is of interest as bearing upon the number of days which must elapse after the contamination of the mosquito before it can convey the disease to a second individual.

An additional point of some importance, I think, is that whereas prior to the time of Moran's infection, (Case V), the contaminated mosquitoes had been taken to the men in their tents and there applied, from this date—December 17th—the subjects were invited to visit a particular room attached to our "Mosquito Building," but quite separate from it, where the contaminated insects were kept at summer temperature, and were there given the opportunity of exposing themselves to an attack of yellow fever by putting their hands inside of certain mosquito-inhabited jars. I may as well tell you know that of seven persons who availed themselves of this privilege five acquired yellow fever.

After a quarantine period, therefore, of nine days, Martinez visited this room on December 17, 1900, and was bitten by fourteen mosquitoes which *four days* before had fed upon Case I of this series. The result was quite negative. December 24th, or on the *eleventh day* after contamination, the subject was again bitten by seven of these insects—all that remained of the original fourteen. Again no infection took place. After six full days, or on December 30th, at 11 o'clock A.M., Martinez was again bitten by the surviving four of these mosquitoes, *i. e.*, on the *seventeenth day* after their contamination. On the fourth day thereafter, January 3d, 1901, at 10.30 A.M., he was seized with yellow fever—which ran a typical course. The period of incubation was three days, twenty-two and one-half hours. Although we cannot say on what particular day these insects became capable of conveying the disease, we are able to state that they were incapable of infecting on the fourth or eleventh day after contamination. This experiment agrees with others that we have made during this investigation and in which we have failed to convey the disease by the bites of insects at intervals varying from two to nine days after contamination. These observations seem to indicate that after the parasite has been taken into the mosquito's stomach, a certain number of days must elapse before the insect is capable of reconveying it to a second individual. This period probably represents the time required for the parasite to undergo its cycle of development and reach the mosquito's salivary glands; and as far as our experience goes, would appear to be about twelve days in summer weather and most probably about eighteen or more days during the cooler winter months. Case VI, therefore, does not support the opinion of Finlay that the bite of the contaminated mosquito confers immunity against a subsequent attack of the disease, since we have seen that neither the bites of fourteen insects on the fourth day nor the bites of seven on the eleventh day after contamination, prevented, in the least, the conveyance of the infection by the bites of four only of these mosquitoes on the seventeenth day.

I will now ask you to look at Case IX, as this case serves to illustrate some points of interest. In the first place, this subject, an American, was bitten by insects that had fed upon Case I of our series on the third day of his illness; that is, during the secondary fever which followed a complete intermission in this case. Secondly, these mosquitoes had been kept alive on sugar and water for a period of *thirty-nine days* before being applied to Case IX. Of the original five insects that had bitten Case I on the third day, four were still alive on the thirty-ninth day thereafter and three showed every evidence of good appetite. Thirdly, this particular subject having passed twenty-one nights in the "Infected Clothing Building," during which time he was exposed to the most intimate contact with fomites, without apparent detriment to his health, had been kept in strict quarantine for yet thirty days longer at Camp Lazear. At the expiration of this time, or on January 19, 1901, at 4.30 P.M., he visited our mosquito room where he was bitten by these thirty-nine-day old insects, three in number. This inoculation was followed by an attack of yellow fever of moderate severity, which began at 4 P.M., January 23, the period of incubation being three days and twenty-three and one-half hours.

Case XII you will find of equal interest, as this individual was infected, in the same room, by the bites of two of these same mosquitoes on the *fifty-first day* after their contamination, the period of incubation being three days and two and one-half hours and the character of the attack mild; while Case XIII will conclusively demonstrate that these identical insects, on the *fifty-seventh* day after their contamination, were not only capable of conveying the infection, but of producing an attack of such severity that the subject's life hung in the balance for several days. I regret to have to state that the individual who had consented to be bitten by these insects on the sixty-fifth day after their contamination, failed to fulfill his promise at the last moment; so that otherwise I cannot say to what old age these mosquitoes might have attained. Deprived of further opportunity to feed on human blood, one died on the *sixty-ninth day* and the other on the *seventy-first day* after their original contamination. The duration of life in the case of these mosquitoes will readily explain how the poison of yellow fever can remain even in a depopulated area for a period of two and a half months; so that, as is well known, those who enter the infected area, even at the expiration of this period, are liable to acquire the disease.

Case XIV is that of our tenth and last successful mosquito infection at Camp Lazear. This individual after twenty-five days' quarantine, having been bitten on February 7, 1901, at 2 P.M., by two mosquitoes on the sixteenth day after their contamination, was seized with an attack of yellow fever at noon, February 10th, after an incubation stage of two days and twenty-two hours.

Thus you will observe that at this station, under strict quarantine precautions, we succeeded in conveying the disease to ten non-immunes by means of the bites of mosquitoes that had previously fed on cases of yellow fever, at intervals varying from sixteen to fifty-seven days before being applied to the person to be infected; that the attack of yellow fever always followed the bite of the mosquito within the period of incubation of this disease, and that during the period which elapsed from December 5, 1900, the date of our first inoculation, till February 7, 1901, the date of our last inoculation (sixty-five days), the order of occurrence of these cases corresponds with the order of inoculation, except that Case II, having a longer incubation period than Case III, the order of their relative occurrence became reversed.

Table I serves to illustrate this point.

By an examination of this table it will be seen that of thirteen individuals whom we attempted to infect

by bites of contaminated mosquitoes we succeeded in ten, or 76.92 per cent. Of the three negative cases, it will be observed that one (Case VI), who had reacted negatively to the subcutaneous injection of 1.5 c.c. of blood on December 26, 1900, also reacted negatively to the bites of mosquitoes on January 8, 1901, and this notwithstanding the fact that he was bitten by the very same insects which nine days before had infected Case VII. We have good ground for the opinion, therefore, that this Spaniard may be looked upon as one who possessed a natural immunity to yellow fever, especially as he was the only one of five persons who did not develop the disease after receiving an injection of blood taken from the general circulation, and was also the only one of five non-immunes who did not contract yellow fever when bitten by insects which already had been proven capable of conveying the disease to other individuals. Case VIII, while negative to mosquito inoculation on December 28 and 29, 1900, reacted positively to a blood injection (2 c.c.) on January 8, 1901. This particular individual, Jernigan, entered our "Infected Mosquito Building" on December 28 and 29, 1900, one week after Moran's visit, and was bitten on each occasion by one mosquito. As sixty-six per cent. of the mosquitoes freed in the building on December 21, 1900, had already been destroyed—most probably by the small red ants that were present in considerable numbers—the subject may have been bitten by insects that were not more than thirteen days old, in which case he would hardly have become infected. While considering the advisability of adding other contaminated insects to those in the house for the purpose of infecting Jernigan, opportunity presented for making a blood injection, and as he was the only available subject in the camp at the time, it was determined to make use of him for this purpose.

Case XIII, our third negative case of mosquito inoculation was bitten by twelve mosquitoes that had fed on Case VII, within eight hours of the commencement of his attack. Although these insects were twenty-two days old when applied to Case XIII, on January 25, 1901, no result followed the bites. As the subcutaneous injection of 2 c.c. of blood taken from the general circulation of Case VII, at the end of twenty-four hours, produced an attack of yellow fever in Case VIII within the period of incubation, it would appear to indicate that the mosquito, at certain periods of the disease, may fail to obtain the parasite owing to its absence, at that particular time, from the capillary circulation. This is not unlike what we sometimes find as the result of an examination of the blood of malarial fever, especially in the æstivo-autumnal type of the disease. Table I also shows that in addition to the positive case (VIII) to which I have already invited your attention, we obtained three other positive results by the subcutaneous injection of blood taken from the general circulation on the first and second days of the disease, viz., Cases VIII, XI, XII. The quantity of blood injected in these three cases was 1.5 c.c., 0.5 c.c., and 1 c.c., respectively. The production of yellow fever in this way is of much scientific interest—first, as serving to confirm what the mosquito inoculations had already shown, viz., that the parasite is present in the general circulation; second, that passage through the body of the mosquito, although this would seem to be nature's method, is not absolutely essential in the life history of this microorganism; and third, that the period of incubation of the disease, when thus produced, corresponds fairly closely to that occasioned by the mosquito's bite. A point of considerable importance brought out by the blood injection was the absence from this blood, on careful bacteriologic culture, of any bacterium which grows on our ordinary media by aerobic methods; thus excluding absolutely the *bacillus icteroides* of Sanarelli from further claim as the specific agent of yellow fever.

Case XIII, our third negative case of mosquito inoculation was bitten by twelve mosquitoes that had fed on Case VII, within eight hours of the commencement of his attack. Although these insects were twenty-two days old when applied to Case XIII, on January 25, 1901, no result followed the bites. As the subcutaneous injection of 2 c.c. of blood taken from the general circulation of Case VII, at the end of twenty-four hours, produced an attack of yellow fever in Case VIII within the period of incubation, it would appear to indicate that the mosquito, at certain periods of the disease, may fail

You will recall that we undertook at Camp Lazear still a third method of propagating this disease, viz., by fomites. I must now tell you that during the whole time that we were producing cases of yellow fever by the bite of the mosquito and by blood injection, we were leaving no stone unturned in order to produce the disease by contact with fomites. Sleeping every night in the "Infected Clothing Building," to which no sunlight ever came, and in which the circulation of air was purposely made as defective as possible; engaged in the morning in packing boxes with garments much soiled by contact with the bodies and excreta of yellow fever patients, and at night unpacking these same boxes in order to obtain articles for their beds and clothing for their bodies; in other words, sleeping in the very beds and garments just vacated by cases of yellow fever, seven non-immune young Americans, averaging each twenty-one nights amidst such uninviting surroundings, came out of this pesthouse,

so to speak, at the expiration of their term, none the worse for their experience. Not one had contracted the disease.

In the light of these results we can hardly be expected hereafter to lend much credence to such observations as that given by Harvey Brown, in 1872,[5] as narrated by Dr. A. A. Baldwin, of Jacksonville, Florida, presumably from memory, some thirteen years after the event. In this instance two children in Jacksonville, Florida, "contracted the disease by being present at the opening of a trunk belonging to their uncle who, a few days before leaving Havana, had visited the yellow fever hospital, where he passed by the beds of those who were throwing up black vomit; and this, notwithstanding the fact that his coat, the only woolen clothing he had on at the time, had been sponged with alcohol after his return from the hospital"'

Or this, recorded by Rochester,[6] as an example "of the wonderful tenacity with which fomites hold the pestiferous material" and afterwards "convey it to mankind with intense effect." "In September, 1856, an infected ship from Cuba was detained at the Quarantine anchorage off Staten Island, N. Y. Several passengers died and some were ill on board. The garments and bedding were thrown overboard. Bay Ridge, a delightful suburban neighborhood of Brooklyn, lies directly across the bay, distant about one mile from the anchorage mentioned. The wind and tide deposited a number of garments that had been thrown away on the beach which terminated the lawn of Col. Charles Prince, an old and respected resident. In taking his usual morning walk he discovered the clothing and examined it with his cane, not otherwise handling it. He had no suspicion that it came from quarantine and never saw it again. In four days he was taken ill and died in a week of yellow fever." We lose our faith in this brine-soaked bedding when we find, according to Elisha Harris' Report,[7] that on the Long Island shore, directly opposite the Quarantine grounds (Bay Ridge) six cases of yellow fever and three deaths from black vomit had already occurred between the 13th and 21st of July, 1856," and that "from the latter date the malady extended fearfully until it had visited nearly every dwelling on the shore of that beautful Bay Ridge, thirty cases and fifteen deaths having occurred in that district previous to August 1."

I could quote many other instances contained in the literature, but as not one of them, as far as my search has gone, will bear the slightest intelligent criticism, I will not further trespass on your time except to say that, in my opinion, every epidemic of yellow fever that has occurred in the United States, both prior to and since the period when disinfectants were used, has pointed in the plainest manner to the innocence of fomites as a means of propagation of this disease; for with the onset of cold weather and under those conditions of lessened ventilation of dwellings and artificial heat that should have aided in the spread of the epidemic, just the contrary effect has always resulted. Under the circumstances, one must either conclude that an external temperature of 32° F. is quite sufficient to bring about, and that speedily, the thorough disinfection of the many tons of infected clothing and bedding contained in the houses of a large city, at the end of an epidemic of yellow fever; or that fomites have no part in the propagation of the disease. The latter conclusion, it seems to me, is the only intelligible one, in view of our present knowledge of the disinfectant action of cold on bacteria.

Let us now see if there are any facts observed by others in connection with the ordinary propagation of yellow fever which support those recorded by us as the result of mosquito bites at Camp Lazear. Since in our limited experience, affecting twenty-three individuals, we have not observed the production of the disease by the bite of the mosquito within less than twelve days after contamination, we would expect that, when a case of yellow fever was imported into a town or house, where the conditions were favorable for its propagation, a secondary case would not occur within a less period of time than about fourteen or more days. I may say that various observers have noted that after the occurrence of the first case in a town, a considerable interval elapses (two or three weeks) prior to the appearance of other cases. Although such general statements are of value, what we need are exact observations recorded under such conditions that the secondary cases can be positively referred to a certain limited source of infection. This, of course, can best be done where the disease has been imported into small settlements or into isolated houses, and it was under just such favorable circumstances that Carter, of the Marine Hospital Service, made his observations at Orwood and Taylor, Miss., in 1898, "on the interval between the infecting and secondary cases of yellow fever." Here, in a community of more than average intelligence, consisting "not of a town, or even a hamlet, but only of a neighborhood," as Carter puts it, it was possible to record with accuracy the date of introduction of the infecting cases and the date of occurrence of secondary cases.

Table II gives the results of this investigation:

TABLE II.

Interval between infecting and secondary cases of yellow fever.

House.	Date of infecting case.	Date of 1st secondary case.	Interval in days.	Next secondary case.	No. of secondary cases.
Orwood, Miss., 1, 1898	Aug. 6	Aug. 23	16½	Aug. 24	6

" " 3, "	" 10	Aug. 25	15	Aug. 28	2
Edwards, Miss., 1897	" 8	" 22	14	" 26	10

This table shows that of sixteen houses in which the interval between the infecting case and the first secondary case was recorded, fifteen, or 93.7 per cent., correspond with the mosquito interval; that is, the secondary cases occur at just the interval—thirteen to twenty-three days—when we would expect them to develop, provided the mosquito was concerned in the propagation of the disease. It will be observed that in only one of the sixteen first secondary cases was the interval as short as eleven days and fifteen hours. If the commencement of the attack in this case has been recorded correctly, it would indicate that the number of days which we have given as "about twelve" for the development of the parasite within the mosquito, would have to be shortened somewhat—probably to ten days. In our first successful experimental case, where the disease was produced by the bite of the mosquito on the twelfth

* 11 days, 15 hrs.

[7] Annual Report of the Physicians of Marine Hospital, 1857.

day after the insect's contamination, we could not say, of course, that this particular mosquito would not have conveyed the infection, had it been allowed to bite on the eleventh or tenth day after contamination.

On the other hand, if we take all the secondary cases that occurred in these sixteen houses, we will find that of a total of seventy-one cases, only one developed the disease after so short an interval as eleven days and fifteen hours: in other words, seventy, or 98.5 per cent., of the secondary cases, occurred after an interval of thirteen days. As a matter of fact only two of these secondary cases occurred within a less period than fourteen days, one developing on the twelfth and the other on the thirteenth day.

I do not know what conclusion you may draw from the data contained in Table II, but to my mind they are strongly suggestive that the same mode of propagation which we were making use of at Camp Lazear during the past winter, was at work in the epidemic of yellow fever at Orwood and Taylor, Miss., during the summer of 1898.

From my own personal experience, I can only add one observation to those given by Carter, viz., at Quemados, Cuba, where of two nurses who remained continuously in attendance upon a case of yellow fever, one contracted the disease on the fourteenth day and the other on the fifteenth day after the commencement of the primary case.

While the temptation is great to extract from the literature other observations confirmatory of those given (and they are numerous), I must refrain from doing this, since I promised to confine myself largely to my own experience in regard to the propagation of yellow fever. For this reason and because I feel that I have already trespassed on your patience longer than I had any right to do, I must omit any reference to the habits of *culex fasciatus*, or of the thermal influences concerned in the propagation of this mosquito, both of which are of much importance in connection with the subject under consideration. I trust that I have said enough, however, to indicate to you that, in my opinion, the ideas which we have heretofore held concerning the propagation of yellow fever must undergo considerable recasting. I do not believe that we can longer ascribe with confidence any part of the spread of this disease to fomites, for under such conditions of intimate and long-continued exposure as could never occur in the natural course of every-day life, we have looked in vain for its development.

While in matters pertaining to the public health, cleanliness should always stand next to godliness, I do not think that we will be justified in assigning so much importance hereafter to those insanitary conditions of soil which, being due especially to pollution with animal matter, were supposed, in some mysterious way, to aid in the spread of this disease. Strange as it may sound, I do not believe that the enforcement of the most rigid hygienic regulations, *such as we have heretofore known them*, will prevent the propagation of this grave epidemic disease, provided it should again be imported into this country. I seriously doubt if we can longer class yellow fever with the "filth diseases." The apparent results obtained by the improved sanitary arrangements instituted by General But'er in the city of New Orleans, during the year 1862, and carried on by his military successors, probably served to strengthen, as much as anything else, the view held by the profession that filth was, if not essential, yet of extreme importance, in aiding the spread of yellow fever. I dare say that but few stopped to consider that General Butler found the city of New Orleans already quite free of yellow fever, and that the same system of blockade which kept this disease out of the former city, under improved sanitary conditions, kept it out of other Southern seaports during the same period, although their sanitary conditions remained unchanged. If one is inclined to believe that improved hygienic conditions, as usually understood, will arrest the spread of yellow fever, let him turn to the city of Havana under American Sanitary Administration. Probably in no city in the world have such unremitting sanitary efforts been put forth as in the city of Havana since our occupation, in January, 1899. We were told that the hard work of General Ludlow and his assistants was responsible for the marked decrease of cases of yellow fever during the first seven months of 1899—and appearances seem to indicate as much—nevertheless, with the commencement of Spanish immigration, during August of that year, and the introduction of susceptible material, cases of yellow fever began to rapidly multiply, so that the city had a late summer and fall epidemic of this disease. Concerning the occurrence of yellow fever in that city during the past year, Major Harvard, Chief Surgeon, Department of Cuba, in a recent report, after describing the thorough work which had been done by the sanitary authorities and its marked effect upon the reduction in deaths, especially from tuberculosis, goes on to say: "It is certain that in Havana, in 1900, no visible correlation could be seen between dirt and yellow fever; the district which became first strongly infected lies east and south of the Parque Central, and is one of the cleanest and best constructed, while the most insanitary wards became infected late in the season and only to a slight extent; the malodorous district reserved to houses of ill-fame hardly had a case. Yellow fever has not followed the poor and unclean, nor the mark of previous infection, but rather the movement of non-immunes; wherever these located, there the infection searched and found them, regardless of the hygienic conditions of their premises."

What is the sanitary story, then, for the year 1900? Simply that with the return of summer weather and the continued influx of new material, and in spite of unremitting efforts to keep the city clean, Havana has experienced a more serious epidemic of yellow fever, affecting its civilian population, than it has had during the preceding twenty years. Need we now express surprise at such a result? Have we not seen at Camp Lazear, under the very best hygienic surroundings, six individuals attacked with yellow fever, after a few short visits to a *new* building whose foundation stood on the unbroken turf and whose rooms were filled with sunshine and with an atmosphere just swept in from the ocean, at the very moment of infection? Where then, gentlemen, shall we look for the agent that is vitally concerned in the propagation of yellow fever? In the light of these newer observations which I have had the pleasure of presenting to you, I believe that we may affirm, with some degree of confidence, that here, substituting *culex* for *anopheles*, we have to deal with the same source of infection to which we now trace the malarial fevers—the mosquito.

A Contribution to the Study of Fatty Metamorphosis.—Franco Carini holds that contrary to the opinion expressed of late by various writers, it appears to be proved beyond discussion that the albuminoids of animal tissues can be transformed into fat. Virchow's classic distinction between fatty degeneration and fatty infiltration is absolutely proved. The differential characteristics between the two forms do not consist in the size of the fat droplet, in the perinuclear arrangement, nor in displacement of the nucleus, but in certain modifications of the nucleus which are constant in degeneration and absent in infiltration.—*Lo Sperimentale.*

EMPYEMA OF THE ANTRUM OF HIGHMORE IN YOUNG INFANTS.*

By EMIL MAYER, M.D.,
NEW YORK CITY,
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, THROAT DEPARTMENT; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, ETC.

THE apparent rarity of this affection, judging from the few cases on record, due, in all probability, to the difficulties in the way of diagnosis, the remarkable unanimity of the symptoms in the cases diagnosed as such, the original methods employed for their cure, and the all-too-brief mention or complete omission in most text-books, should make a study of empyema of the antrum of Highmore in young infants of engrossing interest to the rhinologist. Not more than a dozen cases are to be found in the literature, three of which occurred in this country, and to these the writer now adds another, of which the history is as follows:

Helen May P., aged two and a half years, born in New York City, presented at the out-patient department of the New York Eye and Ear Infirmary on May 11, 1899. Her mother brought her to the ophthalmic department because of an eversion of the right lower lid. The child was examined by Dr. Skeel, who referred the case to the throat department, where it was presented at my clinic. The general symptoms noted were eversion of the right lower lid, a fistulous opening in the cheek on the right side from which pus exuded, and a most penetrating odor from the right side of the nose.

The child had been entirely well until six weeks previous, when an attack of scarlet fever, complicated by pneumonia on the second day, occurred. Two weeks afterward she was taken with what was called diphtheria, very mild in the throat, but very severe in the nose. At the examination made at that time cultures were taken from the throat and sent to the Health Department of New York City. For this report, I am indebted to my assistant, Dr. E. L. Graff, Jr., "A culture taken from the throat on the sixth day of illness failed to show the Klebs-Löffler bacillus. There was a membrane on the tonsils, and a profuse nasal discharge. One injection of antitoxin was given. The inspector of the department says there was much nasal trouble. No record of any other than the Klebs-Löffler bacillus is made by the department."

An abscess formed on the cheek, and was incised May 5. This never healed, and formed the fistulous opening mentioned. An examination showed the left side of the nose to be normal. In the right there was a mass of dry secretion, and a vile odor came from it. The pharynx was normal. A small probe readily entered into the fistulous opening and revealed the presence of a large cavity in a downward direction; there was the feel of necrotic bone. Examination of the pus showed streptococci and staphylococci in abundance, but no Klebs-Löffler nor tubercle bacilli. The general condition was very good, the child being in apparently perfect health otherwise.

A diagnosis was made of an abscess of antrum of Highmore, due to diphtheritic infection. Cleansing solutions were advised, and on June 13 I operated, under ether. An incision was made through the fistulous opening, from left to right, about fifteen millimeters in length; the periosteum was scraped away and all bleeding checked; the fistulous opening in the bone was enlarged by a gouge and the interior thoroughly curetted, all necrotic bone was removed and the cavity washed out. The probe was now bent at right angles and introduced toward the nose, and with a little force it went through the thin bony wall and entered the nasal cavity. This opening was enlarged, and a rubber drainage tube, suitably perforated, was drawn through the external wound and protruded through the nose, so that one end lay on the cheek and the other on the upper lip. The remainder of the incision was sutured. Dry dressings were applied. The tube was pulled out by the child on the second day, and was re-introduced, under ether. Daily irrigations with warm saline antiseptic solutions were employed, and on the seventh day after operation the child left the hospital. Drainage was continued, but the odor had promptly ceased, and on the eighteenth day after operation the tube was removed, and the wound was allowed to heal.

The child has had no further discomfort during the two years which have now elapsed, and no indications whatever of a return of the symptoms have appeared. There is still some eversion of the lid, and a firm cicatrix is noticeable at the site of the fistulous wound.

There are but few recorded cases of this affection in the literature, and they will be briefly mentioned here.

A brief notice of the presentation of a case of empyema of the antrum of Highmore before the Johns Hopkins Medical Society by Dr. Walter B. Platt, of Baltimore, appeared in the *Journal of the American Medical Association*.[1] As a result of correspondence, I am enabled to present the clinical notes of the case through the courtesy of Dr. Platt, which I here gratefully acknowledge.

"Empyema of the antrum of Highmore in an infant of five months of age."[2] The patient, E. L., aged five months, female, entered the Garrett Hospital for Children, Baltimore, Md., December 1, 1899. Both parents appeared healthy, and there was no history of syphilis in them. There was no history of previous disease of any kind in the patient, who had the appearance of robust health. The infant was fat, of firm flesh and good color. Shortly after birth some swelling of the right side of the face was noticed by the mother, with a discharge from the nostril on that side. An opening soon formed on the lower edge of the right orbit a little toward the inner side of the center, from which pus escaped. Pus was soon after seen to escape from the right upper gum, about half-way back. Examination of the patient showed an unusually healthy child. There was no skin eruption, no sign of past or present syphilis on skin or mucous membrane or about anus. Nothing abnormal was noted in thoracic or abdominal viscera. There were no enlarged glands in neck or groin. There was a sinus below the right eye, as noted above. This was adherent to the bone, puffy about the edges, and gave vent to an occasional drop of pus. There was a slight swelling of the right side of the face, hardly noticeable. There was a slight discharge of yellow pus from the right nostril. On the upper gum, about the region of the second molar tooth, was a small sinus from which pus escaped at times. The introduction of a probe showed presence of bare bone. A rudimentary tooth was here removed, and some minute pieces of dead bone removed, when a free opening into the antrum was found. The diagnosis of empyema of the antrum was made, due, in all probability, to gonorrheal infection of the nose during birth. There was no bacteriological examination made of the pus. The discharge diminished rapidly until it was practically *nil*, and the child was discharged December 23, 1899. "She was readmitted January 5th, and was found to have a loose piece of dead bone one-half inch long at the opening of the sinus in the mouth, which acted as a valve to cover the opening and prevent drainage into mouth. This was removed with forceps, and the patient was discharged January 9th relieved.

"She was readmitted February 2, 1900, and a small piece of necrotic bone, half the size of an apple seed, was removed from the outer alveolar wall at the seat of the sinus in the mouth, which was syringed twice daily with boric acid solution, and again the

* Read before the American Laryngological Association at its 23d Annual Meeting at New Haven, Conn., May 28, 1901.

patient was discharged practically well on February 12, 1900. I have made every effort since the last date to see the child, for the purpose of further examination, but as she lives some distance in the country I have been unable to get hold of her."

The first case on record was one reported in 1847 by G. A. Rees.[3] S. R., aged two weeks, had considerable swelling and inflammation in the left cheek, the redness extending round the eyelid, and just below the eye there was an appearance of pointing; the swelling was deep-seated, implicating the floor of the orbit so that the eye protruded to such an extent that the eyelids were incapable of closing over it, the conjunctiva was inflamed and chemosis was present. On opening the mouth the left side of the palate was observed to be depressed, so as to form a tumor on that side, descending below the alveolar ridge; along the dental seam ulceration had occurred, and one of the rudimentary molar teeth was apparent. A rudimentary tooth was extracted, and a director found its way easily into the antrum, its entrance being followed by an inconsiderable discharge of thick matter. On the next day the abscess near the inner canthus was incised. Warm water injected into the antrum from below came out on the cheek. A discharge of pus followed. After some weeks these openings closed and the patient was cured. Rees believed that it was the pressure of the arch of the pubis on the face in parturition that gave rise to the mischief.

D'Arcy Power[4] reports the following history of child of eight weeks suffering from empyema of the maxillary sinus: This child of eight weeks, nursling, showed a pointed abscess below the right lower lid, there was bulging of the entire right side of the cheek, and the skin was red and hot. Pus exuded upon pressure, and a sound introduced into the cavity showed that the upper portion of the maxillary bone was denuded. Power divided the fistula, scraped the granulations, and made an opening through the floor of the antrum into the mouth, drawing through a drainage tube.

Alex. Douglas[5] reports a case of empyema of the antrum in a child three weeks old. The right cheek was swollen and the right eye protruded, presenting the appearance of an orbital tumor. On puncture, over the alveolus, pus exuded. Recovery was complete. Regarding the etiology in this case, there was a possibility of infection of the nose from a sore nipple of the mother, from which pus exuded. Birth was normal.

Roure[6] reports a case of maxillary and orbital osteoperiostitis in a new-born child. A child of fifteen days had a phlegmon of the orbit, with sinus abscess—a spontaneous opening having occurred through the alveolar process of the superior maxilla and at the base of the lower lid. Death occurred in a few days. The affection of the antrum was said to have been occasioned by the entrance of septic secretions in the facial cavities through laceration of skin at the time of birth.

Moure[7] reports two cases, one of Greidenberg and the other his own, in each of which there was an empyema of the antrum in a three-weeks'-old nursling. In Moure's case, there was fistula under the lower lid, swelling of the palate and superior maxillary wall, constant flow of pus from the fistula and nose, formation of sequestra, and the raw denuded bone.

In an article entitled " Tuberculosis of the Upper Jaw in Little Children Simulating Empyema of the Antrum," George Avellis[8] says that "cases of empyema of the antrum in infants have been published by three authors—Power, Moure, and Greidenberg each describing one. The main symptoms of the disease, which was presented as one of very rare occurrence, were a fistulous canal below the lower eyelid, swelling of the palate and the upper wall of the jaw, a continuous purulent discharge from the fistula and nose, formation of a sequestrum, and the recognition of rough denuded bone; finally there was exophthalmos." He doubts the diagnosis in these three cases and positively denies that they were cases of empyema of the antrum. In a typical empyema, he says, "we deal with a purulent affection of the lining membrane of the antrum. The symptoms named above are, however, just such which do not belong to a true empyema, excepting only the flow of pus from one nasal cavity, which is not sufficient justification to assume the presence of an empyema of the antrum. What is the condition, moreover, of the antrum, for example, of a child three weeks old? The antrum is only 0.5 mm deep in the fourth month of life. Previous to this its existence is only theoretical, therefore an empyema of the antrum in an infant is hardly possible on account of the development history." According to Avellis these cases were nothing more or less than a tuberculosis of the marrow-tissue in the nasal and palatinal process of the upper-jaw, in short caries! "As the latter takes its origin from the infra-orbital process, the fistula naturally makes its appearance below the lower eyelid; the thickening of the palatinal process is caused by the caries of its marrow; the formation of a sequestrum, the denudation of the bone, the chronic suppurations, the formation of granulations, the periosteal enlargement of the bone, the slow-healing process, with the expulsion of dead bone—all speak in favor of tuberculosis of bone." He had also observed a case himself, which had previously been diagnosed as empyema. "An abscess developed below the left eyelid in a five-weeks'-old boy. This pointed, and small pieces of bone were expelled through the copiously discharging fistula, while the cheek began to swell. At the same time a purulent and fetid discharge issued from the left nostril. In a hospital the jaw was scraped with an iron spoon after a flap of the skin had been turned back, according to Langenbeck's method, under the diagnosis of empyema of the antrum. Granulations, pieces of bone, and one carious tooth were removed. The wound healed by first intention, the fistula below the eyelid closed with deep retraction and the formation later of ectropion. The nose, however, continued to discharge pus." After this condition had lasted for some time, the child, now one and one-fourth years of age, was brought to Avellis. "The anterior wall of the upper jaw was only slightly swollen, the hard palate, however, markedly bulged into the mouth on the left side. Palpation did not reveal a soft spot. The left nostril contained much pus. A sound passed into the nose revealed the presence at its bottom, namely, the dorsal portion of the palatinal process of the upper jaw, of very rough, sharp and denuded portions of bone. A microscopical examination, which was held later, revealed the presence of a few but distinct tubercle bacilli in the discharge." He emphasized that an acute osteomyelitis of the upper jaw is also frequently mistaken for an empyema of the antrum.

On the other hand, Lenox Browne[9] says, regarding empyema of the antrum in children: "In the first instance these cavities are not strictly sinuses, but rather expansions from the olfactory recesses or pits, budding laterally and posteriorly into the substance of the cartilaginous nasal capsule. An exception is found in the case of the frontal sinus which is developed at a much later period as an offshoot of the anterior ethmoidal cells, penetrating between the

two layers of the frontal bone and quite apart from the nasal capsule.

"The order in which these sinuses appear is as follows: 1, Maxillary at the fourth fœtal month; 2, Ethmoidal at the seventh fœtal month; 3, Sphenoidal at the third year of life; 4, Frontal at the seventh year of life. The maxillary antrum is *well defined at birth*, but undergoes little change until the second dentition, the sixth to eighth year, from which date it develops rapidly in common with the facial bones; but this development is often unequal.

"Several cases have been recently reported of this condition in the infant and *it may occur in the newly born*. At the outset I would say, although the rudimentary character of the frontal sinus of the infant is an argument against its early infection, this by no means follows in the case of the maxillary, albeit it is rare until the age of puberty.

"The cause for such a circumstance is sufficiently varied and direct. In the newly born may be named injury by instruments in delivery; the infection by vaginal discharges of the mother, in an eight weeks old child, and by absorption through the nostrils of purulent secretions from a sore nipple in one aged three weeks.

"It has been suggested that in these cases the disease is not an empyema, but an acute osteomyelitis. The symptoms might possibly represent an acute periostitis due to staphylococcal infection, but the term osteomyelitis is hardly applicable, for at no period of life do these air-cavities partake of the nature of *marrow-holding* chambers, and at early infancy the diploetic walls are so exceedingly thin as to still further exclude the existence of myeloid spaces."

The question thus raised by Avellis having been so effectually answered as regards the question of existence of an antrum at so early an age, and also the impossibility of the occurrence of any medullary inflammation, there remains but to consider the possibility of infection from external sources. In the cases cited in the literature the mode of entrance was taken for granted on the theories of the writers, and hence Avellis might be justified in his unwillingness to accept them. In my own case, here recorded, I have shown how a healthy child, although no longer a new-born babe, within a few weeks after a streptococcus or diphtheritic infection of a marked nature, develops antral disease with all the classical symptoms; and how, after operation with through and through drainage and without further treatment she promptly recovered.

Comparatively few studies of the antra in infectious diseases have been made. Bryan[10] states that empyema of the antrum may occur in the course of the exanthemata, particularly scarlet fever and measles. Lothrop[11] makes the same statement. Harke:[12] In thirty post-mortem examinations of cases of croup, diphtheria, measles, whooping cough, scarlatina and chicken-pox not one was free from suppuration in the accessory nasal cavities, the antrum being most frequently affected.

Moritz Wolff[13] examined bacteriologically the accessory sinuses of twenty-three children who died of diphtheria. In twenty-two examinations of the antrum of Highmore, each case was found affected, there being present either pus or mucopus, or the mucous membrane showing signs of inflammation. When this membrane was œdematous the bacilli of diphtheria were found; when the catarrhal state existed these were absent. In five cases of measles the mucous membrane of the antrum was in a state of glossy œdematous inflammation. The diplococcus lanceolatus and the streptococcus were found and once staphylococci. Three cases of scarlet fever with genuine diphtheria were found with similar results.

Richard Mills Pearce[14] reports the results of the bacteriological examinations, post-mortem, in fifty cases of diphtheria and scarlet fever. The accessory sinuses of the nose, the antra of Highmore particularly were thus examined.

Of the fifty cases examined forty-four were in children between the ages of two and six years. Of the entire number, thirty-nine diphtheria cases were examined; in twenty-five inflammatory changes were present in the accessory sinuses. In sixteen both antra were involved, in five one antrum only. The bacillus of diphtheria was present in all but three of the thirty-nine cases. In one of these cases the streptococcus only was found, and in two the bacillus of diphtheria on one side and the pneumococcus on the other. In two cases the diphtheria bacillus was the only pathogenic organism found; in all others it was associated with one or more of the pyogenic cocci or with the pneumococcus. In two cases of diphtheria with measles the diphtheria bacillus was found in both. In five cases of diphtheria with scarlet fever the antra were normal in three and two contained the bacilli.

These cases indicate that infection of the antrum of Highmore is quite common in fatal cases of diphtheria and scarlet fever. It is probable, in view of its frequency in fatal cases, that it may occur in some cases which end in recovery.

In most cases it clears up without any ill-effects, but it is very possible that in others it may so alter the condition of the lining membrane that later an acute inflammatory condition in the nose may readily set up chronic antral disease. It seems very probable, too, that in those instances in which the bacilli are found persistently in the nose long after the subsidence of all symptoms, we have to deal with an infection of the antrum. In all cases, therefore, in which the diphtheria bacillus persists in cultures from the nose, an examination of the antral cavities would appear to be indicated.

Among the causes of inflammatory conditions in the antra may be mentioned dental diseases, coryza, acute or chronic rhinitis, tonsillitis, and pharyngitis. There may be a secondary infection in typhoid fever, acute rheumatism, suppurative processes in different parts of the body, typhus fever, acute fibrinous and bronchopneumonia, and varicella. The presence of foreign bodies in the maxillary sinus must also be enumerated. Ralph J. Wenner[15] reports a case of disease of the maxillary sinus in a child aged three and a half years occasioned by an erupted tooth. Bacteriological examination of the pus from the antrum showed diplococcus pneumoniæ and staphylococcus pyogenes albus. Careful search was made for tubercle bacilli with negative results.

J. Guttman[16] reports a case of empyema of the antrum in a boy aged five years, occasioned by caries of the teeth and followed by retrobulbar abscess, and he quotes Goodhart as having mentioned a similar case in a boy aged four and a half years.

From the study of the bacteriological examinations and from the recital of cases here recorded, we may conclude that it is established beyond question that empyema of the antrum of Highmore in young children is not merely caries or tuberculosis or osteomyelitis, but is as distinct an affection as in later life.

That so few cases are noted in the living is in all probability due to the fact that the mortality is greatest when this complication occurs, and also that in very young the presence of localized pain is difficult to establish, as the little sufferer cannot indicate it.

In all the reported cases the symptoms are the same,

namely, fistula under the eye usually discharging pus, ectropion, one-sided purulent discharge from the nose with foul odor, and eroded bone. Careful observation, especially in nasal diphtheria when the bacilli are persistent, may enable us to discover these cases and by prompt attention bring about recovery.

Regarding treatment, incision, curettage, and thorough drainage will be followed by complete cure in the vast majority of cases.

THE SELECTION AND STERILIZATION OF MURIATE OF COCAINE FOR SPINAL ANÆSTHESIA.*

By WILLIAM C. RILEY, M.D.,
San Francisco.

Realizing the growing importance of spinal anæsthesia, and some of its difficulties of technique not the least of which is the proper preparation and keeping of the solution of muriate of cocaine—the writer some time ago undertook a series of experiments having for its object the elimination of such difficulty, and now feels at liberty to communicate his final results.

Such questions as relate to the purity, stability and sterility of the cocaine, are easily solved, but that relating to its analgesic action in actual spinal anæsthesia is less easy and has taken time to solve; but now, thanks to the extended use of it in actual work of all kinds, the last question may be considered definitely settled.

I have personally witnessed over two hundred unselected cases of spinal anæsthesia for all purposes, where cocaine selected and prepared in the manner to be described was used, and, in which the dose has never exceeded three-tenths of a grain, without one failure in securing complete and prompt (four to five minutes) analgesia lasting from one and one-half to three hours.

Here, as in all other fields of investigative work, to get uniform results we must commence with everything exact and uniform; hence in this instance we must begin with what we know to be a pure dry muriate of cocaine—a chemically pure product. Unfortunately, in this drug there are many variations in strength and purity furnished by the manufacturing chemists.

Who of us would think of taking any and all of the various products in the market for general anæsthesia simply because they bore the label chloroform? So with muriate of cocaine, which even varies more in its composition as marketed than does chloroform.

I cannot more fittingly enforce this statement than by quoting from a paper read before the New York Pharmaceutical Association at its twentieth annual meeting in July, 1898, by F. R. Tuthill, and reported in the transactions and also in the *Druggists' Circular and Chemical Gazette*, Volume 42, Number 8. These results it suffices to say, I have personally confirmed.

This article strongly drew my attention at that time whilst endeavoring to explain the lack of uniform results in the use of cocaine in minor operations, as regards especially its variable toxicity, on some other basis than the convenient but often misleading term personal idiosyncrasy. I will abstract in brief from Mr. Tuthill's paper, referring those who desire more detail to the original.

"It is most natural that we should establish, as a basis of any discussion, the fact that the therapeutic activity desired when cocaine hydrochlorate is administered is due entirely to the cocaine contained. that is to say, the anæsthetic effect which is desired from any preparation of cocoa leaves is dependent solely upon the particular alkaloid to which the name of cocaine has been given — this degree of intensity of effect will, consequently, be diminished in exact proportion to the amount of any other substance, either inert or active, which may be present; when cocaine hydrochlorate which is sold by one manufacture differs in the intensity of its action from that sold by another this difference is due to the fact that one brand contains more impurities than the other. In comparing these several brands we find the variance in the total cocaine present will be from ninety per cent. to one hundred per cent. of the theoretical quantity, and that there are differences in color from perfectly white, which is the proper color, to greyish yellow, or light brown. It should be odorless—yet in some occaine hydrochlorate a tobacco-like odor is faintly or, in some, strongly noticeable. (I will state that in one brand on the market, otherwise pure save for a slight, variable amount of water of inclusion or absorption, a peculiar sickening aromatic odor is present, which, however, is dissipated on dry heating.)

"One class of impurities is more or less harmless—the inorganic substances, such as sodium, potassium, or calcium compounds, used in the process of manufacture—they act as worthless adulterants of a costly medicament, and render exact dosage impossible." "The secondary alkaloids form the other class of adulterants—there appear to be, in certain varieties of the coca leaf, notably coca cultivated in Java and Ceylon, which leaves are more largely used in making cocaine, besides the alkaloid cocaine, a certain amount of two secondary alkaloids, which have been designated cinnamyl-cocaine and isa tropyl-cocaine—therefore these two secondary alkaloids are natural diluents.

"Cocaine as it exists in the coca leaves is readily decomposed into secondary alkaloidal compounds — produced by drying the leaves or through fermentative changes, which take place when baled and shipped. They are also produced by breaking down of the cocaine during the process of purification and separation. We must therefore conclude that the preparation of a pure cocaine salt is not by any means an easy matter.

"Some of these secondary alkaloids are possessed of very decided physiological action, and this of an undesirable kind. This particularly applies to isatropyl-cocaine, which tends to depress the heart, and has absolutely no anæsthetic action. Dr. J. M. Francis has

*Read before the Medical Society of the State of California at the 31st Annual Meeting, April, 1901.

informed me that there is cocaine hydrochlorate on the market containing as high as three to four per cent. of this secondary alkaloid."

In view of these facts can it truthfully be said that cocaine poisoning is always due to cocaine, or failure to get spinal analgesia due to any inherent fault in the method? I think not. When there is added to these uncertainties the other factor of variable amounts of decomposition products, inert, if not otherwise harmful, caused by the methods of sterilization in solution, can it be wondered at that some operators report twenty-five per cent. of failures to get complete analgesia.

In choosing a muriate of cocaine, one should select that occurring in anhydrous, well defined, rather large, colorless, and nearly odorless crystals. Silky, hydrated crystals containing two molecules of water of crystallization are not fit for the purpose, inasmuch as they lose in containers other than air-tight from seven to nine per cent. of their weight, hence are not constant, and, unless previously subjected to drying process at 212° F. for twenty or thirty minutes, interfere materially in the after preparation.

The large anhydrous crystals contain, on an average, from one to three per cent. of water of inclusion and absorption; usually, if broken up and air-dry, about one per cent. Each original package, after the crystals have been reduced in a mortar to a moderately fine powder, should be subjected at least to the following very elementary test for the detection of isatropyl-cocaine, the most deleterious of all constituents the cocaine is liable to have, because it is a very active cardiac depressant, and must undoubtedly either contribute to or cause many instances of heart failure from the use of cocaine—largely so in minor operative work, where it is, in many instances, so rapidly absorbed. Unfortunately this most important test is omitted from the U. S. P., 1890, and for such reason I offer it in full. It is known as Maclagan's ammonia test.

Dissolve 0.1 gramme muriate of cocaine in 87 c.c. of distilled water, and then add three drops of ammonia (ten per cent.); for a few moments the solution will remain clear, but rapid stirring with a glass rod will cause a prompt crystalline precipitation of free cocaine, leaving a solution free from milkiness behind. If isatropyl cocaine is present, a milky turbidity will ensue immediately on addition of the ammonia; if other impurities are present, they will prevent the crystallization of the cocaine. This proportion makes a good test, but one grain to two ounces of distilled water is sufficiently exact, crystallization taking place in one-half to three-quarters of an hour. In making this simple test, precaution must be taken to have the cocaine fully dissolved and in sufficiently dilute solution, as above; otherwise, the milkiness will show when no isatropyl-cocaine is present. The other tests are standard in the U. S. P., 1900, to which I refer, merely mentioning the requirements of neutrality to litmus.

Many, indeed the large majority of chemists and physicians, believe, and it is astonishing how deeply rooted this belief is, that muriate of cocaine is readily decomposed by heat, few knowing how the dry salt may be raised to and maintained at a dry sterilizing temperature without losing a particle of its peculiar anæsthetic qualities. Such is the fact, however, and I have formulated, after bacteriological and practical work on animals and the human subject, a method by which this can be done.

Briefly reviewing the methods of sterilization adopted by the many operators to-day, they all are, with one exception, based on the more or less prolonged action of heat on a solution of muriate of cocaine at from 80° to 81° C. (176-177° F.) to 100° C. (212° F.), for from one minute, which does not sterilize, to fifteen minutes, which destroys much of the cocaine present, and even then does not fulfill the requirements of perfect sterilization.

Some operators do not sterilize at all, and it is to be noted in such reports that they have no failures in analgesia; but we certainly are not justified in such a course. One man who reports quite a number of obstetrical cases carries the cocaine crystals weighed out by an apothecary, in ordinary powder papers covered by tinfoil. Another orders the druggist to make up a two per cent. solution and uses it as it is. Still another whose method, as he naively states, may not be wholly free from bacteriological objections, but is practically so, rubs up the powdered crystals with ether, maintaining the rubbing until the ether is all evaporated. He is correct in his statement that it is not free from bacteriological objection—as I have satisfactorily demonstrated for myself.

Keen, of Philadelphia, because of the difficulties with cocaine, has adopted eucaine, which permits of sufficiently prolonged boiling to sterilize without decomposition. But almost every other operator fails to get analgesia with eucaine even in considerably larger dosage than cocaine.

The method of Tuffier, consisting of fractional sterilization of a two per cent. solution, preferably in sealed tubes, for three successive days at 80° C. for fifteen minutes each time, is at present the most satisfactory in every respect. It gives a perfectly sterile product provided everything—funnels, filters and containers—is thoroughly dry-sterilized before. Likewise the least amount of cocaine is destroyed, hence the solution is more active for a given dosage, but like all solutions of cocaine it rapidly deteriorates and at the end of ten days or two weeks is practically unfit for use. This factor necessitates constant preparation to keep on hand an efficient solution, and for one who perhaps might use it a few times per month makes the task a somewhat irksome one.

As an offset to those manifest disadvantages the writer offers a method of dry-sterilization which fulfills all requirements.

Carefully selected muriate of cocaine is broken in a mortar into moderately fine fragments and heated in a dry sterilizer to 110° C. for about twenty minutes and then bottled in a clean, dry bottle with a tightly fitting rubber stopper. This insures a dry salt to begin with, which is quite essential for the after-process. Small graduated vials or glass tubes are taken and carefully cleansed, dried and flamed, and when cool such an amount of the cocaine is weighed off into each as will make, when when the vials are filled to this mark with sterilized water a two per cent. solution. The mouth of the tube is then closely stoppered with a plug of freshly dry-sterilized absorbent cotton (150°—160° C. for one hour). It is then placed in a dry sterilizer and the temperature gradually raised to from 145° to 150° C. (293° to 302° F.) and maintained at that temperature for from ten to sixty minutes. Ten minutes is usually sufficient time to fulfill all bacteriological requirements, but there might be a possibility of contamination with certain spores which would require the longer period.

One hour's heating of this dried cocaine at this temperatur does not impair its efficiency, notwithstanding many statements in the books to the contrary. After cooling, the vials may be taken out at one's leisure, and after the cotton plugs have been withdrawn with sterilized forceps, be stoppered with sterilized rubber stoppers, or, which I prefer, ordinary well-fitting corks which have been plunged in a wax resin mixture heated to 170° C. (338° F.); or the end

of the tube softened in the flame, drawn out and sealed.

To sum up the advantages offered in this method of preparation:

1. Perfect sterility.

2. The product being dry lasts an indefinite time, the only thing being necessary when required for use is to sterilize the outside of the container in any convenient manner except boiling—as, for instance, simply flame the cork and neck of the vial, allowing it to become cool before adding water.

3. No necessity to weigh or measure the cocaine or water at the time of the operation.

4. Absolute efficiency.

This method is so simple that the author hopes it will be generally adopted not alone for spinal, but for any kind of cocaine anæsthesia where perfect sterility is advantageous.

A CASE OF PRIMARY EPITHELIOMA OF THE UVULA.*

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK CITY,

INSTRUCTOR IN LARYNGOLOGY, UNIVERSITY MEDICAL COLLEGE; LARYNGOLOGIST, UNIVERSITY MEDICAL COLLEGE DISPENSARY; CONSULTING LARYNGOLOGIST AND OTOLOGIST OF THE HEBREW SHELTERING GUARDIAN SOCIETY ORPHAN ASYLUM.

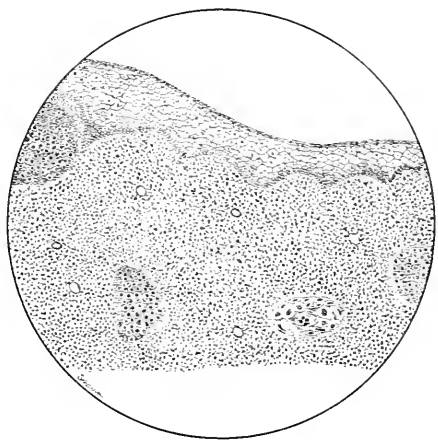
The primary development of an epithelioma in the tissues of the uvula is of extremely rare occurrence. So infrequently does this occur that Lenox Browne[1] states that he has seen but one case of malignant disease arising primarily in this location. His patient being a man, forty-eight years of age, in whom the uvula presented the apperarance of a thick warty mass with all the characteristics of an epithelioma. The adjacent glands were not involved and the entire growth was removed successfully. Microscopically, it consisted of typical stratified epithelial growths with small cell infiltration. There was localized activity of the surface epithelium which had invaded the subjacent tissue in cylindrical form, and there existed marked inflammatory changes.

Walker Downie[2] has also reported a case of this nature in a man of fifty-six years, who suffered from difficulty of swallowing, pain and impaired breathing for two months previous to the examination. The uvula was enlarged, ulcerated, and bled on the slightest touch. The adjacent glands were not involved and the epithelioma was limited to the free portion of the soft palate. Removal was successfully effected with cocaine anæsthesia and no recurrence had taken place at the time of the report, seventeen months after operation.

The following case occurring in my practice was diagnosed as one of primary epithelioma of the uvula, and presents features of interest allied to the two cases previously mentioned

T. T., a man aged eighty-one years. Referred to me by Dr. Yates, of New York. The family history was negative, with the exception of a brother, who died of malignant disease. The mother and father both lived to advanced age. All his relatives, both near and remote, have been noted for their longevity. He has always enjoyed good health until a few years ago, when, following an attack of coryza, he developed bronchitis from which he has since suffered. Two years previous to the time when I first saw him, he had a stroke of apoplexy, with right hemiplegia, slight paralysis of the side still being present. He has complained, for a year or more, of irritation of the throat. He was examined at various times by his family physician with negative results, until a few weeks ago when a thickening at the tip of the uvula was noticed. This continued to increase until I saw him, when examination revealed a growth the size of a walnut, involving the entire uvula from its tip to its junction with the soft palate. The adjoining tissues presented nothing abnormal; the growth was bluish-red in color, not ulcerated, and firm to the touch. The cervical glands were slightly enlarged, but not tender, and the only symptom complained of, in addition to those noted, was slight pain radiating to the ears.

A small piece of the growth was removed for examination and the report of the pathologist, Dr. E. K. Dunham, confirmed my diagnosis of epithelioma. The sections removed for microscopic examination were stained after the usual methods and showed the stroma to be the seat of considerable inflammatory



reaction, while the epithelial cells were arranged as in a typical picture of epithelioma, with the presence of nuclear changes as shown by numerous mitotic figures indicating rapid cell proliferation. (See accompanying illustration).

On account of the age of the patient, the glandular involvment, and his general impairment of health, operative interference was not considered advisable.

Although the prognosis is necessarily grave in epithelioma of the upper respiratory tract, yet in the few cases that have been recognized early and in which all the diseased tissues were removed, the favorable result, for a time at least, of operation would warrant a brighter outlook than has heretofore been given. In the case of a patient in good physical condition, primary epithelioma of the uvula, if removed early, presents but little tendency towards recurrence, but if surgical measures be adopted, as late as in the case here reported, especially with the glandular system showing involvement, rapid recurrence is the rule. Of interest in this connection is the fact that the location of the growth seems to exercise a restraining influence upon the natural tendency of this form of malignant disease to spread. In consequence of the histological structure of the uvula, an epithelioma usually originates in the muciparous glands and for a considerable time is limited to these structures; sections of the uvula showed the tubulated arrangement of the proliferating cells.

*Presented at the Seventh Annual Meeting of the American Laryngological and Otological Society at New York, May 25, 1901.

[1] Diseases of the Throat. Fifth Edition.

[2] *Glasgow Medical Journal*, February, 1898.

Ulceration of a primary epithelioma in this region does not usually take place until very late in the course of the disease; the absence of ulceration accounting for the trifling annoyance the affection produces until the growth has increased in size sufficiently to interfere with swallowing. The loss of free movement of the uvula produces faulty phonation, and, as the movement becomes still further restricted by the growth increasing in size, liquids have a tendency to enter the choanæ.

Pain is not a prominent or constant symptom in the early development, and when it does occur it is irregular and not at all severe; the contrary is the case, however, when the disease has involved other tissues and ulceration has taken place. Usually the most constant feature complained of by the patient is the slight faucial irritation due to a moderate inflammatory reaction and to some œdema which usually accompanies the malignant changes.

706 Madison Avenue.

MULTILOCULAR CYST OF THE INFERIOR MAXILLA; OPERATION; RECOVERY.

By J. A. OTTE, M.D.,

Amoy, China.

The patient was a well-nourished lad of sixteen, appearing older than he really was. He would have taken him to be at least twenty-two years old. He had a hard, bony tumor involving the greater portion of the inferior maxilla, viz., the lower part of the right ramus, and the whole of the body on both sides up to the insertion of the second molar on the left side. The teeth were in perfect position and were all present except the second bicuspid on the right side, which was wanting. The growth of the tumor was downward, backward, and inward. After removal it was found to be four inches in diameter from right to left, two and one-half inches from above downwards, and two inches through the symphysis. On the right side of the face was a sinus extending down to the bone, the result of an effort to remove the tumor with caustics. The history was indefinite, but the patient said the tumor had been growing for about two years. There had been no pain, but articulation was becoming indistinct and swallowing difficult. There was no evidence, whatever, of the tumor being cystic. Indeed, after removal it was found that, except for numerous small cysts the size of a pin-head to that of a bean, the whole of the enlarged alveolar process was practically solid while the rest of the bone was cystic. An operation was performed on January 2, 1901, by the writer and Dr. C. Johnson. Tracheotomy below the isthmus of the thyroid was attempted, but as this organ extended almost down to a level with the top of the sternum, it became necessary to cut through the cricoid cartilage. This part of the operation was very tedious and annoying. Three small sponges were then pushed down into the larynx and the diseased bone was removed by disarticulating the right side and sawing between the second and last molar on the left side. It was only while dissecting off the tissues on the inner side of the tumor, near the attachments of the tongue, that the cystic nature of the growth became apparent. Here in one place the bone had been absorbed, leaving about one-half inch of the bony cyst simply covered by periosteum. The outer surface was exceedingly vascular, causing much delay. On the third day after the operation the tracheotomy tube was removed. A silk thread was passed through the tip of the tongue at the time of the operation. It was only by pulling the tongue forward by means of this silk thread that the patient was able to swallow for about a week after the operation. The main portion of the wound healed by primary union. The exception was where the sinus in the cheeks had been cut out. This healed by granulation. The temperature was normal until the morning of the third day, when it rose to 100°. After this until the ninth day it ranged between 98.2° and 101.2°. On the evening of the first day the pulse was 140 and small. It gradually improved in character until the ninth day when it was 92, where it remained until the patient was discharged.

By January 29, the patient was practically well, but still quite weak. Articulation was very indistinct.

On February 8 there appeared a swelling on the left side extending from just above the mastoid process down to the middle of the sterno-cleido-mastoid muscle. It was feared this might be a recurrence, but it proved to be only an abscess which, after opening, slowly healed. This abscess kept the patient in the hospital until March 5, when he was finally discharged. After removal, the tumor was sawn through near the symphysis. In the section fifteen large and small bony cysts were seen, the largest the size of a dove's egg. These did not communicate with each other. Besides this, on cutting through the bony portions numerous other cysts were found. In order to preserve the specimen further section was not made, hence many of the smaller cysts were probably not discovered. These cysts contained a glairy, brownish fluid. In some cases the walls were smooth, and in other cases lined with interlacing trabeculæ. The sinus in the face led into one of the cysts, which was suppurating.

I have been able to find but little on the subject of multilocular cysts of the lower jaw in the books available.

Typhoid Fever.—M. S. Shellenburg says that more has been accomplished by the prophylactic treatment of typhoid fever than by the cure, by protecting our streams and water supplies from contamination, and making our drainage perfect. Typhoid fever is most prevalent in cities in which the drainage is bad, and startling results are shown from statistics taken before and after perfecting the drainage in a city. As long as a privy-well has not become contaminated by the typhoid bacillus there is no danger of typhoid fever. This theory explodes the theory of auto-intoxication, which is that an individual may become a prey to the disease without coming in actual contact with the typhoid bacilus. The excreta is the contagion bearer and should therefore be thoroughly treated before being disposed of. Great care should be taken in protecting the permanent part of the bed, such as the mattress, and this can be done by spreading a rubber blanket or a mackintosh over the mattress. Ordinary boiling will destroy the germs in the bed clothing and linen of the patient; the stools, however, must be treated specially. Bi-chloride of mercury in the proportion of one part to five hundred of water is the best disinfectant for use in the country, but it will not do for the linen, as it stains the latter. In cities, carbolic acid, one part to ten, answers the purpose best. Chloride of lime, one to twenty-five, has rather a pleasanter odor than carbolic acid. Whitewash, twelve parts unslacked lime to one hundred of water, is useful in the country, where it is most available. Sulphate of iron, a tablespoonful to a pint of water, has been used. The buttocks, anus and genitalia of the patient should be washed after the bowels have been moved, in a 1–2000 bi-chloride of mercury solution. Door-knobs, clinical thermometers etc., which have been handled, should be cleansed in a 1–1000 solution of the same.—*Medical Times.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 10, 1901.

THE CLAIMS OF HYDROTHERAPY IN MODERN MEDICINE.

THE use of water in the treatment of disease is as old as mankind. Its employment in fevers is usually thought to be a purely modern method, and yet, in the Rig-Veda, which is assigned to 1500 B. C., we find it stated that "Water cools the fever's glow." Hippocrates, we are told, held water in high favor as a remedial agent, and the invention of the shower bath is commonly ascribed to Asclepiades of Prusa in Bithynia (B. C. 128–56), though Pliny says that we are indebted to Sergius Orata for the primitive form of this device. Nearly all the ancient medical writers, including Celsus, Aretæus, Agathinus, Aetius, Galen, Herodotus, Charmis of Marseilles, Rhazes, and Avicenna speak with appreciation of the use of water in medicine.

The first attempts at scientific hydrotherapy, as contrasted with the purely empirical methods of the ancients, were made at the beginning of the eighteenth century, when Johann Sigismund Hahn (1696–1773), a Silesian physician, published his work, "Unterricht von der Wunderbaren Heilkraft des Frischen Wassers." James Currie (1756–1805), originally an American merchant, who became a physician in Liverpool, was the first to use water in the treatment of febrile diseases according to modern methods, *i. e.* with regard to its effect on the pulse and the temperature. With the ascendance of rational therapeutics, the names of Andreas Pleninger, F. Runge, and Wilhelm Winternitz became coupled with hydrotherapy, and certain forms of "water cure" became the popular rage as the result of the efforts of a Silesian peasant, Vincenz Priessnitz, (1799–1851), and of a German country priest, Sebastian Kneipp (1822–1897).

In America hydrotherapy was first introduced in 1843 by Dr. Russell Thatcher Trall, of Vernon, Connecticut (1812–1877) and Dr. Joel Shew, of Providence, New York. To-day no name is more closely associated with hydrotherapy in America than that of Dr. Simon Baruch, of New York.

At a recent meeting of the Philadelphia County Medical Society, Dr. Baruch delivered an address entitled "Lessons of a Decade in Hydrotherapy," in which he pleaded for a wider diffusion among physicians of accurate knowledge concerning the effects of cold and heat, as applied through the medium of water, upon the human system in health and disease. No one who is interested in the progress of medicine can help joining in this appeal. Every physician uses water as a remedy to a certain extent, but we agree with Dr. Baruch when he says that many still do so in a haphazard or purely empirical manner. The physiological effects of water used at different degrees of temperature and pressure and for varying intervals of time are now thoroughly understood thanks to the researches of Winternitz, Brandt, Rhovigi, Baruch and others, and there is no more excuse for empiricism in hydrotherapy than there is for the haphazard ways in the use of drugs whose physiological effects are known.

The trouble has been heretofore that some of our best clinicians have looked askance upon any attempt to apply hydrotherapy in a way that would seem to place drugs and other methods of treatment in the background, because "water cure" has so often been associated in their minds with quackery. It is time to recognize that hydriatrics rests upon a secure scientific basis, and that whilst rational therapeutics repudiates any attempt to make water the only remedy for every ill, the physician who wishes to cure his patients cannot afford to neglect this arm in the battle against disease.

It is therefore the duty of practitioners to become acquainted with the theory as well as the practice of hydrotherapy, to further the teaching of this branch of medical art in a thorough and practical manner in the medical schools, and to strive for the correction of the popular misconceptions regarding the use of water as a remedial agent.

DISCRIMINATION AGAINST THE ARMY MEDICAL CORPS.

WE referred in a recent article to the injurious effect upon the Medical Corps of the provisions regarding it in the army reorganization bill passed during the last session of Congress, and we endeavored to show that the only remedy for the injury so done was the restoration of the Medical Corps to a position equal at least to that of the other departments in the Army. Congress seemed to take an especial delight in degrading the medical department, so far as it could do so by making the majority of its officers of lower rank than those of the other departments. In the Judge-Advocate-General's department—the lawyers' branch of the military service—for example, the new law authorized the appointment of lawyers from civil life to the grade of major; a grade which the same bill prevented the doctor newly appointed from civil life from receiving until after more than a quarter of a century of hard service. One of these places in the Judge-Advocate-General's department was recently filled by the selection of the son of a prominent politician—the appointee to the grade of major being twenty-seven years of age, or younger than the average medical man who enters the service as a first lieutenant.

The plea advanced for the higher grading of officers of some of the other staff departments was based upon their great pecuniary responsibilities and the necessity of having a sufficient number of officers of high rank for the administration of a *personnel* of enlisted men. The fact was overlooked by Congress that the property for which army medical officers must be responsible is greater than the property responsibility of any staff corps outside the Quartermaster's Department; while the enlisted men of the Hospital Corps—4,500 in

number at the present time, who have to be trained, disciplined, drilled, and commanded by medical officers, were five times greater in number than the enlisted strength of all the staff departments of the army combined—formed a greater force than nine full infantry regiments before the war with Spain, were almost equal to the entire artillery force of the United States at that period, and equaled three-quarters of its cavalry force; that it was more than half as large as the enlisted strength of the entire United States Navy, and was nearly twice as large as the Marine Corps. The fact that medical officers of the Army held independent commands in charge of hospital ships and the many large general hospitals—some of the latter more than twice as large as any military post or garrison in the United States—was conveniently ignored. Congress made no adequate provision as regards rank for the medical officers, who are constantly called upon to settle administrative questions requiring certainly as high an order of executive ability as is required in the line or other staff departments.

It is a curious commentary on the intelligence of Congress that promotion in the Army Medical Corps should have been cut down in this way in the year 1901, when in the year 1900, because of the lack of candidates for the Navy Medical Department, it had been found necessary to increase the inducements for young medical men to enter that service, and raise their grading and pay to that which was then enjoyed by their professional confrères in the army. The bill just passed reduces the Army Medical Department to almost exactly the conditions which had to be relieved in the Medical Department of the Navy by legislative action during the preceding session of Congress, and which the experience of a generation had demonstrated would not permit of a thoroughly efficient medical service.

SOME ETIOLOGICAL ASPECTS OF MALIGNANT NEOPLASMS.

THERE is not wanting evidence indicative of the parasitic origin of malignant disease, as exemplified in various forms of new growths, but, despite the industry and the persistence with which investigation along this line has been pursued, conclusive evidence is yet wanting. The difficulties in the case are not lessened by the fact that a satisfactory explanation is lacking also for the origin of the so-called typical, homologous, or benign neoplasms, as well as for their occasional transformation or degeneration into malignant growths.

Apparently the two most important etiological factors in connection with malignant disease are heredity and traumatism. Next in importance perhaps is sex, but, as Dr. E. N. Nason (*British Medical Journal*, May 18, 1901) points out, the great preponderance of malignant disease in women is found, on examination, to be due to the great frequency with which the uterus and the breast are involved. Thus of 4,855 cases of carcinoma occurring in 1 837 males and 3,018 females, one or the other of these organs was the seat of the disease in 40 per cent. of the women. Excluding these cases, the disease appears to be rather more common among males than females, and this difference may be attributed to the greater liability of males to traumatism especially. Statistics show further that the increase in mortality from carcinoma that has been observed in the last thirty years is almost twice as great in males as in females. This increase is not entirely real, but is due in part to greater skill in diagnosis, particularly with reference to malignant disease of the stomach, to which a large proportion of deaths from carcinoma in men are due. At the same time the mortality from malignant disease of the uterus and the breast has been lessened in consequence of the great advances that have been made in surgical treatment.

Analysis discloses also that after the third decade the individual liability to carcinoma of the stomach, the breast, or the rectum increases progressively to the eighth decade and then declines; while the liability to carcinoma of the uterus rises rapidly and progressively to the sixth decade, when it is double that of the other, and then declines.

There are reasons for believing that carcinoma develops under conditions in which the resisting power or the vitality of the cells of the body has been in some way lowered, so that invasion by a parasitic organism is favored; and it is thought that this may take place in one or more of several ways, *e. g.* absorption from the intestinal tract, absorption from the respiratory tract, or direct inoculation either through abrasions of the skin or mucous membranes or the bites of blood-sucking insects.

THE INCREASE OF QUACKERY IN GERMANY.

GERMANY is often credited with being the home of all that is most deeply erudite and most truly scientific in medicine. And yet German authors are pained to admit that the fatherland is infested by an increasing number of arrant quacks, commanding an astonishing amount of confidence at the hands of the paying public.

Despite all warnings and protests from reputable practitioners, a drift away from legitimate medicine, not unlike our own Christian Science movement, is clearly recognizable in German countries. Possibly this heretical tendency, like other widespread delusions, will have to run its course. Healthier views are bound to prevail in the long run. Meanwhile it may be comforting to us to know that the Germans have their osteopaths, their "natural" physicians, their herbalists, their "water doctors," their Christian Scientists and their "new system" men of all kinds, who flourish at the expense of legitimate practitioners.

In a recent address,* Dr. Tschlenoff, of the University of Bern, once more examines the claims of the various faddists who profess to be benefactors of the human race, but who actually make a good living by exploiting the credulity of mankind. Dr. Tschlenoff wastes no words on the well-known methods of out-and-out quacks. His argument is directed against the claims put forward by that large class of uneducated pseudo-doctors, who use the so-called "natural" methods of therapy, and thereby pretend to accomplish far more than the graduates of universities and schools of medicine. The author clearly shows that whatever is actually beneficial in physical

**Naturheilkunde und Wissenschaftliche Medicin.* Stuttgart, F. Enke, 1901.

methods has always been known to medicine, and forms part of the curriculum of our medical schools.

The prophets of so-called "naturalism" in medicine, like Kuhne, Platen, Schroth, Bilz, and Kneipp, have merely brought into vogue in a more or less dramatic way, methods used as adjuvants to treatment by regular physicians from time immemorial to the present day. It is really humiliating to be compelled seriously to take up the preposterous claims to recognition so often and so loudly made by the various classes of charlatans, who masquerade as unselfish "healers," "bone-setters," "nature-doctors" (*Naturärzte*), and what not.

Anatomy, physiology, pathology, and skilled diagnosis are all alike unknown to these pretenders. And yet in Germany, as in our country, they base their impudent demands to recognition on systems of treatment that disregard utterly what is most essential in rational medicine. They say they heal where doctors hurt, and that therefore they are not only the equals, but rather the superiors, of trained and diplomaed medical men. The general public is always ready to admit that if a clock or any inanimate piece of mechanism goes wrong, a skilled artisan is needed to examine and properly repair the damage. But if the human body, that most delicately constructed mechanism, is out of order, we are called upon to believe that the accurate knowledge of its normal workings can be dispensed with. As Dr. Tschlenoff justly remarks, it deeply shames the boasted intelligence and enlightenment of our times that such monstrous claims have to be refuted again and again.

It is well known that in Germany the ranks of the "natural healers" are recruited from the lowest classes of society. For example, the official figures for the city of Berlin show that sixty per cent. of unqualified practitioners were former day-laborers or artisans, and only forty per cent. had had an even elementary school education. Of female healers, fifty-eight per cent. had been servant girls. Moreover, Professor Guttstadt has shown that about thirty per cent. of Berlin's irregulars had a criminal record.

It ought to be understood once for all that air, water, massage, the various forms of exercises, Swedish movements, electricity, dietetics, and the whole range of non-medicinal methods of treatment possess no mysterious virtues, hidden from the ken of licensed practitioners. And yet it is only too true that even the educated classes are often willing to follow the precepts of some arrant pretender, while neglecting the sound advice of a regular physician.

It is very unfortunate that whenever and wherever reputable physicians expose the crass ignorance of these self-appointed "healers," the public suspects the unselfishness and purity of professional motives. It speaks well for our profession and its great traditions that despite the obstacles thrown in their way, honorable physicians have not yet wearied of attempting to teach mankind how to protect itself from danger and spoliation at the hands of these alleged benefactors of the race. And so we may hope that the present increase of quackery in Germany is but a passing phase and that the public will not forever play the facile dupes to increasing bands of arrogant knaves and fools.

YELLOW FEVER SPECIFICS.

MANY years ago Maclagan, when writing of the virtues of salicin in the treatment of rheumatism, put forth the theory that where any disease prevails endemically there nature has provided a specific remedy. In support of this he instanced the curative effect of cinchona bark in malaria, and of willow bark in rheumatism. We are reminded of this by two reports, coming from different sources but published nearly simultaneously, on the use of indigenous plants in the treatment of yellow fever. Dr. T. P. Porter, of Kingston, Jamaica, writing in the *Detroit Medical Journal* of July 25, says that the "bush" doctors of Hayti and other West India islands use with almost invariably satisfactory results vervain (*Verbena officinalis*) and guinea-hen weed (*Petiveria alliacea*) in the treatment of yellow fever among the negro natives. This is, he says, the same remedy spoken of by Spence in his "Land of Bolivar," published in 1878. Another remedy is the seed of *Simaba cedron* or *Quassia cedron*, a tree of Central America, preparations of which have long been employed in the treatment of snake-bite and the stings of insects and also of malarial fever. Dr. S. H. Hodgson, of the Marine-Hospital Service, writing from Progreso, Mexico, in the *Public Health Reports* for July 26, says that he has tried this remedy in several cases of yellow fever, and from the results obtained concludes "that it is as specific for yellow fever as quinine is for malaria;" and so convinced is he of its value in the treatment of this disease that he asks to be sent to some place where yellow fever is epidemic so that he may be able to give the drug a thorough trial. If yellow fever is a plasmodial disease analogous to malaria, as the experiments of Major Reed and his associates on the Army Commission in Cuba would indicate it is, there is no inherent improbability in the supposition that a specific remedy for it exists somewhere in nature. It may be that this remedy is the active principle of Simaba cedron or verbena, or possibly of both plants, and we shall be glad to learn of the results of a further trial of cedrin, if that is the active principle of cedron seed.

THE TEACHING OF ANÆSTHESIA.

WE have but recently (MEDICAL RECORD, June 15) called attention to the importance and the desirability of including instruction in anæsthesia in the curriculum of the medical schools, and it is gratifying to note that inquiries have been addressed to the various hospitals of London with regard to this matter. It is understood that the subject of anæsthesia will soon be included among the compulsory branches of study, so that every student, before being admitted to a qualifying examination, will be required to furnish evidence of his competency to administer anæsthesia in an ordinary case. To the same end it is said, teachers of anæsthesia are being appointed in the reorganized University of London. The step thus taken is a most important and commendable one and it deserves general imitation.

The Plague has reappeared in Sidney, N. S. W., one death having been reported there on August 6.

News of the Week.

Convention of Health Officers in New York State.—The State Health Department is making arrangements for a convention of health officers and registrars of vital statistics of the State, to be held in Albany on October 24 and 25. There are 1,400 local health boards in the State, each having a health officer and registrar of vital statistics. Papers will be read on the subjects of sanitation, public health, water supply, sewerage, vital statistics, etc.

A German Investigation of Bovine Tuberculosis.—A commission was appointed by the German Government in July to examine the results of Koch's experiments on bovine tuberculosis, and to make other experiments in order to determine definitely the exact relation between human and bovine tubercle bacilli. Among the members of this commission were Professors Virchow, of Berlin, and Bollinger of Munich. The Berlin papers warn their readers not to accept the views enunciated by Prof. Koch until they have been substantiated by other investigators, and say that precautions for preventing the spread of tuberculosis by milk must not be relaxed.

The "Oklahoma Medical News" is the name of a new monthly journal published in Oklahoma City, and edited by Dr. J. R. Phelan. Its first issue, for July, gives promise of a long and useful future.

Ward Thirteen Abolished.—It is reported that the authorities at the Binghampton State Hospital have done away with Ward 13, because of the depressing effect the unlucky number had on some of the patients.

The Eyesight of School Children.—Dr. Wallace Pyle recently reported to the Jersey City Board of Education the results of an examination of the eyes of 1,215 pupils in five public schools of that city. Of these 1,215 pupils, 205 had defective eyesight.

Change in the Sanitary Squad.—On the first of next January the policemen composing the sanitary squad of the Health Department of this city will be sent back to patrol duty, their places being filled by one hundred men selected, after a civil service examination, from the general body of police.

Robbery in a Smallpox Hospital.—A man and his wife have been arrested in a New Jersey town for robbing the smallpox hospital—which was empty of patients—of bedding, china and glassware, linen, and nearly everything portable.

Antitoxin in Zion.—The trouble into which Dowie and several of the inmates of his "Zion" have fallen of late through the deaths from diphtheria of faith-treated children has injected considerable caution into his methods. The health authorities of Chicago were surprised a few days ago by the request from Dowie for diphtheria antitoxin. The remedy was applied in several cases in which the faith-cure treatment had been followed by an aggravation of the symptoms, and a cure resulted.

An Investigation of the Baltimore Hospitals has been undertaken by the Mayor of the city, on account of the case of a man who died in jail of alcoholism after admission at a number of hospitals, including Bayview Asylum, the city institution for poor people, had been refused to him. The man was found in the street acting as though insane, and suffering from a cut over one eye, having been knocked down by a wagon. He was taken to the Baltimore University Hospital, but the officials there refused to allow him to remain. The patrol wagon then carried him to St. Joseph's Hospital, where admittance was also refused to him. The City Hospital would not receive him because, it is stated, the institution was full. Johns Hopkins Hospital also refused to take him. Two hours after the man was taken to jail he died.

The Randall's Island Quarantine.—For the past three months Randall's Island, where there are several public institutions, has been quarantined because of the prevalence of smallpox, the only means of communication between the inmates of the various institutions and their friends ashore being through the mails. It is announced, however, that the embargo will soon be lifted and the institutions will again be open to visitors.

An Epidemic of Broken Legs.—The morning papers on Monday last, reported a curious coincidence in the way of accidents. Three women on their way to or from church, slipped on banana peels on the sidewalk and fell, each breaking her left leg.

Rush Medical College, which has been made the medical school of the University of Chicago, will hereafter admit students of both sexes. At present women will be admitted only to the two lowest classes, but in a year the two upper classes also will be open them.

Notification of Tuberculosis.—The Health Department of Jersey City has notified all physicians of that city that they must hereafter include pulmonary tuberculosis among the contagious diseases to be reported to the authorities.

An Orthopedic Home in Boston.—Mr. A. C. Burrage, of Boston, has leased Bumkin's Island from Harvard University for 399 years, and will build a hospital on it and make it a free Summer home for the crippled children of Boston. This island lies half way between Nantasket and Hingham, and about one and a quarter miles north of Hull. It was given to Harvard College by Samuel Ward, who was a friend of John Harvard, but has never been used to any advantage. It contains about fifty acres of ground available for hospital purposes.

Smallpox among Indians.—Reports received by the Department of the Interior at Washington, state that smallpox prevails extensively among several tribes of Indians, notably the Flatheads and Winnebagos, and the most stringent measures are necessary to prevent the spread of the disease.

Consumptives to be Barred.—It is reported that the authorities of St. Luke's Hospital contemplate closing the consumptive wards in the hospital and using the forty-two beds which they contain for patients ill with acute diseases.

The State Manufacture of Antitoxin.—Dr. H. D. Pease, of Yale College, has been appointed director of the State Laboratory for the manufacture of various prophylactic and therapeutic sera, and for the serum and bacteriological diagnosis of infectious diseases.

The Financial Results of American Sanitation.—In the course of an editorial comment on one wing of the few but vociferous pessimists who can see nothing cheerful in the financial or political horizon, *The Times* of this city has something to say of the marvellous work accomplished in Havana in the two years and a half that American medical men have had sanitary control of the city. "There has been," this appreciative writer says, "no death from yellow fever

in Havana since March 16. In the month of June there was not a case of the disease, a thing that has not been reported before since 1781—one hundred and twenty years ago. Santiago is free from the disease. It has not been free from it before for three hundred years. Yellow fever usually comes to us from Havana. Whenever it effects a lodgment in the Southern States business is always seriously interfered with all over the South, and in many cities and towns it is practically suspended—sometimes as a result of the shotgun quarantine. The whole country feels the consequent loss and injury to trade. New York is the worst sufferer. It is a low estimate to say that a visitation of yellow fever costs the country $100,000,000. A limited and comparatively brief interference with our vast inter-State trade easily involves the loss of that sum; and if the epidemic is severe and prolonged it is much greater. Now it is highly improbable that we shall have any yellow fever this year—more improbable than in any year for a century or so. This is one of the results of the joint despotism of William McKinley and Leonard Wood over the island of Cuba—whose people are and by right ought to be free to have all the yellow fever they want, according to the anti-imperialists. But that is another question and aliunde. Our present purpose is to gloat over the hundred million dollars we are going to save by not having yellow fever this year."

"Le Caducée" is the name of a new journal published in Paris under the editorship of Dr. Granjux, with the assistance of Dr. E. Laval. The *Caducée* is Mercury's wand, and this journal, which takes its name, is to treat of military medicine and hygiene, including tropical diseases.

Charged with Illegal Practice in New Jersey.—The State Medical Board of New Jersey, through Dr. John W. Bennett, of Long Branch, one of its members, caused the arrest of five physicians on July 31, for practicing illegally in Monmouth County. All of the physicians but one, Dr. A. H. Friedenberg, of New York, waived examination. The physicians were accused of having failed to file a certificate of license with the Clerk of Monmouth County. At the trial, on Saturday last, Dr. Friedenberg proved that he had passed the examinations of the board in 1896, and in June, 1897, before beginning practice at Hollywood, filed his certificate with the County Clerk. Judge Schoenlein dismissed the complaint, exonerating the physician.

The American Association for the Advancement of Science will hold its fiftieth annual meeting at Denver on August 26 to 30, under the presidency of Dr. Charles Sedgwick Minot, of Boston. The first session will be opened at 10 o'clock on Monday morning, August 26, by the retiring president, Dr. Woodward, who will introduce the president-elect, Dr. Minot. Addresses of welcome will be made by Governor Orman of Colorado and Mayor Wright, of Denver. Honorary President J. B. Grant will introduce Gen. Irving Hale and Aaron Gove, who will welcome the association on behalf of the business men of Denver and the educators of Colorado. On Monday afternoon the vice-presidents' addresses will be delivered by Professors John A. Brasher, Allegheny, Pa.; Charles B. Davenport, Chicago, Ill.; Amos W. Butler, Indianapolis, Ind., and Calvin M. Woodward, St. Louis, Mo. A reception will be held on Tuesday evening, following the presidential address of the retiring president, Dr. R. S. Woodward. Section meetings will be held on Tuesday, Wednesday, Thursday, and Friday. Numerous excursions are planned to give members of the association an opportunity for field work. Several important questions will be brought up at this meeting. It has been suggested that the salary of the permanent secretary be fixed at $5,000, or else one or two assistants should be provided for. Another suggestion is a change in time of the meetings from summer to the Christmas holidays, unless, perhaps a summer meeting be held, say, every three years. Several amendments to the constitution may also come up for consideration. The most important changes are a provision that the president and secretary of each affiliated society be made members of the council, and that a new section on commerce and manufactures be organized. The proceedings of this meeting, when published, will constitute the fiftieth volume, and an important part of the business of the meeting will be to arrange for the making of a general index of the fifty volumes by the general secretary, Professor L. O. Howard.

The New York Central Tunnel.—As a result of a recent investigation, the Grand Jury has brought a presentment in regard to the Park avenue tunnel, calling upon the Board of Health to use its powers to cause an abatement of the nuisance.

The Surgeon-General of the Navy.—The term of appointment of Dr. W. K. Van Reypen, Surgeon-General of the Navy, will expire on December 18. There is not much talk of his successor yet, as it is very generally believed and hoped that he will be reappointed to serve until November, 1902, when he will be retired under the age limit.

Pennsylvania State Medical Examination.—Of four hundred applicants for license to practice medicine examined in June last by the Pennsylvania State Medical Board one hundred failed to pass.

The Jury of Awards at the Pan-American Exposition, with respect to all exhibits having to do with hygiene and sanitation, medicine and surgery, has just concluded its labors. The chairman of the jury was Capt. E. L. Munson, Assistant Surgeon, U. S. Army, whose recent book on military hygiene has been favorably noticed in these columns; and the members were Surgeon S. H. Griffiths, U. S. Navy, lately attached to the Naval Museum of Hygiene, Washington, D. C., and Professor S. H. Woodbridge, Professor of Heating and Ventilation at the Massachusetts Institute of Technology, Boston, Mass., and now acting as Government expert for the improvement of the ventilation of the Capitol building at Washington. A large number of exhibits were submitted to this jury for consideration, the awards being based upon the character and quality of the exhibits as actually made at the Exposition. The exhibits in the section on public health are said to have been found to be of a high degree of excellence.

Mosquitos and Malaria.—The New York City Board of Health has prepared a circular of instruction regarding the relation of mosquitos to the spread of malaria, and the best means of exterminating these pests. It advises the drainage and filling of all pools of stagnant water, and the treatment by oil of those which cannot be drained. It is to be hoped that the board will follow its own advice and do away with the breeding-places of mosquitos, which are very plentiful in some of the outlying parts of the city and especially in the Central and other public parks in the several boroughs. Mosquitos have been unusually numerous in Fordham Heights during the past month

and simultaneously with their appearance there have been many cases of malaria. The region is on elevated ground and has none of the traditional aspects of a malarious district. Dr. Alvah H. Doty, the Health Officer of the Port, has inaugurated a campaign against mosquitos on Staten Island in the vicinity of the quarantine station, the object being to determine the possibility of exterminating the insects in a given region, and the effect such extermination would have on the prevalence of malaria. A preliminary survey of the region has brought to light many cases of malaria and has shown the presence of the anopheles among the mosquitos and of their larvæ in stagnant pools. The pools, cesspools, and other natural and artificial collections of stagnant water will be subjected to the oil treatment, and the results as regards the health and comfort of those living in the neighborhood will be carefully noted. A report of a successful experiment comes from Camp Jackson, New Orleans, where formerly mosquitos were in such overwhelming numbers that life for the small garrison maintained there was almost intolerable. A free use of crude petroleum has been made with the result that, from being one of the worst places in New Orleans, it is now the freest from mosquitos of any part of the city.

The Medical Society of the Missouri Valley.—The fourteenth annual meeting of the society will be held in St. Joseph, Mo., on Thursday, September 19, and Eureka Springs on Friday and Saturday, September 20 and 21. Papers have been promised by a number of men from Chicago, Omaha, and New York, in addition to those to be presented by members of the society. The president is Dr. V. L. Treynor of Council Bluffs, Ia., and the secretary Dr. Charles Wood Fasset, of St. Joseph, Mo.

The American Electro-Therapeutic Association will hold its eleventh annual convention in Buffalo, on September 24, 25, and 26, 1901. Its headquarters will be at Hotel Niagara, and its place of meeting the Armory of the 74th Regiment.

Aseptic Dueling.—In order to make a safe practice doubly safe, French duelists have of late taken to the sterilization of their swords, and now it would be considered as reprehensible for a duelist as it is for a surgeon to omit "the usual antiseptic precautions. In an account in the New York *Times* of a recent duel between young Daudet, the son of the novelist, and a journalist of Paris named Richard, it is said that after the first attack, the point of Daudet's sword accidentally touched the ground, when the seconds intervened and stopped the contest until the blade could be disinfected, Afterwards Daudet was wounded in the wrist, but thanks to the antiseptic precautions taken by the seconds, he is doing well, and will soon be able to use his sword arm again in defense of his honor.

The New York Milk Supply.—The Health Commissioners have held several conferences with the officials of railroads carrying milk into New York, and as a result of the conferences the greater part of the milk used here is to be shipped in refrigerator cars stocked with a sufficient supply of ice to keep the temperature of the milk at or under 45° while in transportation. Some time ago the health authorities undertook to have the milk cooled by ice while in transportation from the dairies to the city, and the officers of several railroads consented to make up their milk trains of refrigerator cars. They put no ice in the cars, however, and consequently the milk has been coming to the city at a temperature of from 70° to 80°. The Milk Commission of the New York County Medical Society has awarded certificates to five large dairies which are keeping the bacteria in their milk down to 30,000 in the cubic centimetre.

Poisoning by Moon Seed.—Three boys died in convulsions some time ago in Sharon, Pa., after eating some berries which they had found growing on a vine. The symptoms resembled those of strychnine poisoning, and suspicion was directed against a farmer of having drugged some cider which the boys had stolen and drank. Some of the berries, found in the pocket of one of the boys, were sent to Philadelphia and were identified as moon seed (menispermum canadense). The plant is not a common one. The leaves are partially peltate, palmately lobed, and resemble in form those of the English ivy, but are much smaller and thinner. It is a climbing plant, is of slender growth, reaching the height of about ten feet in the season, and is sometimes cultivated as an arbor vine. In the fall and winter there is nothing to be seen but the clusters of shining black berries, resembling the "frost grapes," for which children may readily mistake them.

A Smallpox Hospital for the Well-to-Do.—The suggestion has been made that the erection of a smallpox hospital for private patients would be a very useful and profitable undertaking. At present all those attacked by the disease, irrespective of their social position or the means at their disposal, are removed to the public hospital on North Brother's Island. It is believed by those in favor of the scheme that next winter, unless the Board of Health is more active or more successful in fighting the disease, there will be a veritable epidemic of smallpox in this city, and that then, when too late to establish one, the need of a private hospital for the isolation and treatment of pay patients will be most apparent.

A New Bactericide?—The Detroit papers say that considerable interest has been aroused at the University of Michigan over certain experiments demonstrating the bactericidal action of nascent oxygen when freed within the body from certain organic bases. The experiments are being conducted by Dr. Frederick G. Novy.

Professional Secrecy Violated.—A Paris physician was recently fined 200 francs and sentenced to pay the plaintiff in a suit against him 1,000 francs damages. The plaintiff was taken suddenly ill at the house of the parents of his fiancée, and in response to the questioning of the young woman's mother the doctor told her the nature of the patient's illness. This led to a breaking off of the engagement, and the young man sued the physician for breach of professional secrecy, with the result as stated.

A Nurse for over Sixty Years.—Mme. Bottard, of Paris, has recently been pensioned and decorated with the cross of the Legion of Honor after having served for nearly sixty-two years as nurse in the Salpêtrière. She entered the hospital in 1840 on a salary of 12 fr. a month, and in all the years since, it is said, she was outside of the hospital but twice, and each time got lost in the maze of Paris streets. She is now eighty-three years old.

Abuse of the Cigarette by a medical lecturer has led to a suit for damages against a Louisville medical college. According to a Chicago paper, the professor denounced cigarette smoking in his lectures in no uncertain terms, and, not content with that, also characterized cigarette makers in very uncomplimentary, not to say unparliamentary, language. The students took offence at this, and struck against attendance at the professor's lectures until he had apologized to such as indulged in the cigarette habit. This he declined to do, and then the faculty, taking

alarm at the students' stand, turned the professor away, and he thereupon sued the college for damages to the amount of $15,000.

Obituary Notes.—Dr. Henry Buckingham Horlebeck, of Charleston, S. C., died in that city on August 2d following an apoplectic attack from which he suffered in the spring, soon after his return from Havana where he had been attending the Pan-American Medical Congress. He served as surgeon in the Confederate Army during the Civil War, and for twenty years had been health officer of Charleston.

Dr. P. Calvin Mensch, professor of biology in Ursinus College, died of tuberculosis at Collegeville, Pa., on July 30, at the age of thirty-seven years. He was a graduate of Ursinus College in 1887, of Bellevue Medical College in 1890. He received the degree of Doctor of Philosophy from the Grant University, Tennessee, in 1891. He had been since 1894 at the head of the biological department at Ursinus College, and was an authority on the subject of marine annelids.

Dr. Gilbert E. Palen, of Philadelphia, died of pneumonia at Ocean City, N. J., on July 27, at the age of sixty-nine years. He was a native of Palenville, N. Y., and a graduate of Yale in 1853 and of the Albany Medical College in 1855.

Dr. James V. Kendall died at his home in Baldwinsville, N. Y., on August 5, at the age of eighty-three years. He was a graduate of an eclectic medical school in 1851. He was during the Civil War surgeon of the One Hundred and Forty-ninth New York Volunteer Regiment, and served a term as member of the State Assembly in 1869.

Book Reviews.

Diseases of the Thyroid Gland and Their Surgical Treatment. By James Berry, B.S. (Lond.), F.R.C.S., Surgeon to the Royal Free Hospital, etc. Philadelphia: P. Blakiston's Son & Co., 1901.

This volume is largely a record of personal experience in the pathology and surgery of the thyroid gland. However the author has drawn on all sources of material relating to the subject, and has produced a very readable book. He discusses his subject systematically, beginning with the anatomy of the gland and considering in order the various forms of disease to which it is subject. Perhaps the most interesting section of the volume is that devoted to the consideration of the distribution of goitrous disease in England. The conclusion reached is that air and climate have nothing to do with the causation of goitre, but that drinking water containing some undiscovered calcareous ingredient plays an important rôle in this regard. This view prevails also to a great extent among Swiss surgeons. Naturally the most important part of the treatment of goitre is surgical, and to the different forms of this the author devotes much space and introduces descriptions of many clinical experiences. The accidents and post-operative complications so important in thyroid surgery are commented upon and proper warnings are given. The author has had much experience in thyroid surgery and his opinions are valuable. He has introduced many excellent illustrations, which add to the usefulness of his book, and has introduced at the end a table of statistics upon one hundred consecutive operations.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By James Nevins Hyde, A.M., M.D., Professor of Skin, Genito-Urinary, and Venereal Diseases, Rush Medical College; and Frank Hugh Montgomery, M.D., Associate Professor. Sixth and Revised Edition. Illustrated with 107 engravings and 27 plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co., 1901.

It does not seem so many years ago since the Medical Record first noticed Dr. Hyde's book. It was not nearly so good a book in those days, but it showed promise. As we have been called upon to look over succeeding outputs of the work we have year by year found more to commend and less to criticize. The pathology has gradually undergone changes which has made necessary frequent alterations in this portion of the book. Illustrations have been freely added until now the suggestion might be made of substitution rather than of leaving in all the old when new plates were added. Among the diseases whose chapters have been rewritten are acne, herpes, psoriasis, blastomycosis, carate, tuberculosis, scleroderma, zoster, etc.

The well-known clinical observations upon blastomycotic dermatitis made by these authors renders the chapter on this subject especially interesting. The hand of the junior partner is evident in some of the revision work and the original author is to be congratulated on having associated with him so able a worker and writer. We are glad the success we predicted for this work years ago has been so prompt and so complete, and we trust it may continue for many years to come.

The International Medical Annual. A Year Book of Treatment and Practitioner's Index. Nineteenth Year. New York: E. B. Treat & Co., 1901.

The only thing we can say against this yearbook is its fine print. This is rendered necessary, of course, by the vast ground covered unless the material were collected in several volumes or one double the size. The present volume has 682 pages. The usual ground is creditably covered, and in addition we find special articles on toxins and antitoxins; one on Tuberculosis by Prof. Ruata of Italy; one on the Rœntgen rays, by Macintyre of Glasgow; one on Color-blindness, by Eldridge Green, and one on Dental Surgery, by Mr. Turner. The general high standard of accuracy and completeness is being maintained.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles. Edited by H. W. Cattell, with the collaboration of J. B. Murphy, A. D. Blackader, H. C. Wood, J. M. Rotch, E. Landolt, T. G. Newton, C. H. Reed, J. W. Ballayntine and John Harold. Vol. I. Eleventh Series. Philadelphia: J. B. Lippincott Company, 1901.

Twenty American and European physicians of note are represented in this collection. The therapeutical department has this time "Notes on New Remedies," by A. G. Stevens; of Philadelphia; "Treatment of Gleet," by A. Renault, and "Treatment of Eczema," by Hallopean, both of Paris. Dr. W. H. Walmsley gives some practical methods in photomicrography. In 100 pages Dr. Blackwood reviews the progress medicine has made in the past year, adding a most useful chapter to the list of clinics.

A System of Physiological Therapeutics. Edited by Solomon Solis Cohen, A.M., M.D., Professor of Medicine and Therapeutics in the Philadelphia Polyclinic, etc. Volumes I. and II. Electrotherapy by George W. Jacoby, M.D., Consulting Neurologist to the German Hospital, New York City. Philadelphia: P. Blakiston's Son & Co., 1901.

The first volume deals with electo-physics and the apparatus required for the therapeutic and diagnostic use of electricity. Interest naturally centres in the Röntgen rays, and on p. 210 we find a chapter on properties, sources and effects of the rays; tubes, machines and all down to *x*-ray burns. Considering, however, the great importance in diagnosis and its growing value in therapy, the chapter is all too short. The work is well illustrated and has been written in a most painstaking and highly scientific manner.

This second part of Dr. Jacoby's work includes diagnosis and treatment and is freely illustrated. There are only 182 pages to the work proper, but, with the additions of the use of electricity in eyework by Edw. Jackson; in surgery by J. Chalmers Da Costa; in throat, nose, and ear by Wm. Scheppegrell; in gynecology by F. H. Martin, and in skin by A. H. Ohmann-Dumesnil, quite a good-size volume is presented.

Some of this additional work of special nature does not add as much to the value of the whole as one might be led to expect, and there is some reiteration. The chapter on electricity in cutaneous surgery fails to reflect (as an up-to-date work of this kind should) the great value of the various methods now so well known to dermatologists. Much space which might have been utilized is wasted in cross-references which serve no good purpose. Nevertheless, the two volumes of Dr. Jacoby's work make an excellent introduction to this new system, and if all the rest come up to the standard he has set its success is assured.

L'Immunité Vaccinale. Par Le Docteur Maurice Coste. Paris: J. B. Baillière et Fils, 1900.

The subjects chiefly treated in this brochure are the occurrence of variola in the non-vaccinated, in those vaccinated, and in those re-vaccinated, whether successfully or not; also the course of the disease when it attacks those

who have already had variola; the rôle of vaccinal immunity in modified variola, the effects of age on the variolic receptivity, and the prophylaxis of smallpox. It is thus seen to be a most interesting topic and one appearing at a time to attract some attention in the United States, where recent mild epidemics have given rise to no little controversy on these very points.

RUDIMENTS OF MODERN MEDICAL ELECTRICITY, Arranged in the Form of Questions and Answers and Prepared Especially for Students of Medicine. By S. H. MONELL, M.D., Professor of Static Electricity in the International Correspondence School; Founder of the New York School of Special Electro-Therapeutics. New York: Edward R. Pelton, 1900.

THERE are one hundred and sixty-five pages of these questions and answers not intended for quiz use, evidently, but to bring out certain points of fact and of belief. Any one who has not given much time to medical electricity who will read carefully these questions will pick up considerable information.

MEDICAL AND SURGICAL NURSING. A Treatise on Modern Nursing from the Physician's and Surgeon's Standpoint, for the Guidance of Graduate and Student Nurses, together with Practical Instruction in the Art of Cooking for the Sick. Edited by H. J. O'BRIEN, M.D. New York and London: G. P. Putnam's Sons, 1900.

THE author has based his instructions on personal experience with nurses. The articles are written by physicians, with the exception of that on cooking, and reflect the medical standpoint in giving instruction to students in nursing and—as the writer states—the competent nurse no less than the physician should always be a student The work can be recommended to all student nurses.

TRAITÉ DE CHIRURGIE, CLINIQUE ET OPÉRATOIRE. IX. VESSIE, URETHRE, PROSTATE, PENIS, ENVELOPPES DU TESTICULE. Par FÉLIX LEGUEN, J. ALBARAN et PIÈRRE SEBILEAU sous direction de A. LE DENTU et PIÈRRE DELPET. Paris: J. B. Baillière et Fils, 1900.

THIS volume (ninth) is given up to the surgery of the genito-urinary passages and organs. There are two hundred and forty-five illustrations in the text, which covers nearly a thousand pages. The chapters have been prepared with much care as to detail and the anatomico-pathological features have been given much attention. The writers in in charge of these subjects have succeeded in keeping them well up to the standard set by preceeding volumes.

HEART DISEASE IN CHILDHOOD AND YOUTH. By CHARLES W. CHAPMAN, M.D., Durh., M.R.C.P., Lond., with an introduction by Sir SAMUEL WILKS, Bart., M.D., F.R.S. London: The Medical Publishing Company, Limited, 1901.

A NEAT little book with a few pictures, charts, and tracings giving an outline of the usual varieties of cardiac disease in early life. Especial stress is laid on hygienic management.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HEAT WAVE—TUBERCULOSIS CONGRESS—NATIONAL HOSPITAL—EPSOM COLLEGE—DISCUSSION ON ALCOHOL—PATHOLOGICAL SOCIETY AT OXFORD—BACTERIOLOGY OF RHEUMATISM—RUPTURE OF THE UTERUS IN PLACENTA PRÆVIA—INVESTITURE BY THE KING—RECENT DEATHS—WEATHER, GREAT STORMS—THE TUBERCULOSIS CONGRESS—THE OPENING BY THE DUKE OF CAMBRIDGE—DR. KOCH'S STARTLING STATEMENT—THE JOINT DEBATE OF TWO SECTIONS ON TUBERCULIN—DR. BROUARDEL'S ADDRESS—BANQUET TO KOCH—RECEPTION OF FOREIGN DELEGATES BY THE KING

LONDON, July 19, 1901.

HOT waves and whence they come have been the table-talk of the week. Many hold that they come direct from your side, but there seems no reliable evidence that they travel across the Atlantic. Our newspapers have given us particulars of your suffering from them day by day. Compared with the temperature here we ought not to feel so oppressed by a short spell of hot weather, as the majority of us do; for myself I am salamander enough to enjoy it. It is true that the week has been a hot one—the hottest for a long time, but people would not feel it so much if they adapted their diet and regimen to it. A noteworthy point is that the heat has been prolonged to a later hour than usual. There has been a good deal of cloudless sky, and the direct rays of the sun have softened the asphalt and melted the tar of the wood pavement in certain streets. The thermometer crept up to 90° F. in the shade. Numerous cases of syncope and heat-apoplexy have been treated at the hospitals, and there have been some fatalities. Horses, too, have suffered much. Reports from the provinces are of the same kind.

Another topic is the Tuberculosis Congress, which is to be held next week. It has this association with the foregoing subject: Some hearty condemnation is afloat of the folly of fixing it in the dog-days, especially as it is to be held in London. But, further, it is followed by the British Medical meeting the next week. Though that happily is in the country. After all, these meetings are fixed for what is called the holiday season. That is all very well for the consultants, but the masses of the profession only smile dolefully when you speak of August as a vacation month.

The National Hospital controversy may be regarded as closed. At a special meeting the Governors adopted the report of the Investigation Committee. The Secretary-Director has resigned, as the Committee advised that the office be abolished. The Governors also decided to appoint a committee to carry into effect the recommendations of the report. This is a sort of mixed committee on which two representatives of the staff are to sit, three of the Managing Board and four of the Committee of Selection. Perhaps they may be "a happy family." Their business will be to revise the rules and reorganize the government of the institution. In any case, the staff must be represented on the future board So far, the staff has vindicated its rights and upheld an important principle of hospital management.

Lord Rosebery, as President of the Royal Medical Benevolent College, took the chair at the twenty-eighth festival dinner on the 9th inst. In his speech, he suggested that the adjectives "medical" and "benevolent" should be omitted. He paid a handsome tribute to the profession, to which he said all owed a debt which they could neither limit nor estimate. Dr. Holman, the treasurer, thought the adjectives might very well be omitted if the position of the pensioners and foundation-scholars were made secure. They could wipe out benevolence, if the supporters would provide some £50,000, but he could not as treasurer agree to do so without that security. The difficulties he had to meet each year convinced him that people would not give without a *quid pro quo*. It was painful to him to say so, but it was true.

Now John Propent founded Epsom College for the benefit of the medical profession, and its chief supporters belong to that. The pensioners have no reason to be ashamed that they are supported by benevolence, and the boys have no occasion to blush that their fathers were doctors who had met with misfortune. This sentimental objection to the word benevolence seems to me absurd and its expulsion might possibly be a step toward the gradual misappropriation of a foundation, such as has too often been the history of other institutions which have survived through many generations to benefit persons who were not intended to be recipients of its benevolence.

Professor Sims Woodhead is an earnest leader in the crusade against the abuse of alcohol. He opened a discussion at the Edinburgh Medico-Chirurgical Society on the 3d inst. with the query "Is alcohol a poison, a drug, or a food; or if, as some think, it is all three, in which rôle it is most important?" No one denies that it is a narcotic poison, and Dr. Woodhead said it is a protoplasmic poison. As a drug it is not a panacea, and he held that it should be prescribed with as much care as other medicines. The notion that it is a food he considered responsible for most of the diseases it produces. Admitting that it is oxidized in the body and might thus supply some heat, no sane man would put it forward as able to supply the number of calories required and easily obtained from fat and carbohydrates Dr. John Madden recently showed that the latter exerted no toxic effect, while alcohol is a violent protoplasmic poison. Instead of protecting nitrogenous tissues from undue waste, as do fats and carbohydrates, it actually increases their waste. Further its avidity for oxygen is a factor in producing some forms of fatty degeneration and that, too, without any accompanying nutrient action. It is on account of this absence of a nutrient element that the cells do not become accustomed to the poisonous action. The tissues consequently do not become immune to its effects. Referring to the combined action of arsenic and alcohol, the professor said that tissues weakened by one poison are more easily injured by another; alcohol, in some way, also acts as a predisposing cause to specific infective diseases. The normal resistance of rabbits to streptococcus pyogenes erysipelatis is greatly diminished by previous dosing with alcohol, and this agrees with our clinical experience. Similar facts have been shown as to anthrax, tetanus, rabies, etc.; as to phthisis, there is direct evidence that alcohol predisposes to the disease; it can therefore hardly be good as a

permanent food substance. In two cases of acute alcoholism in young healthy persons, Dr. Woodhead found acute myocarditis. The effects on nerve-cells were also described.

Professor Fraser then took up the cudgels on behalf of alcohol, said the effects of small and large doses were entirely different, and because of its easy oxidation alcohol might give energy and so be of use in certain crises. He then proceeded, after the manner of professors of materia medica, to relate its effects on the circulatory and other systems. As to nutrition, it was more easily consumed than fats or carbohydrates. It was absolutely burned up in the body, and therefore must generate energy and must be a food substance. But this last statement seems a *non sequitur* and merely contradicts Dr. Woodhead without refuting him. As to infection, Dr. Fraser said plague in Calcutta among a teetotal population gave a mortality of ninety-five per cent. against twenty per cent. among Europeans consuming alcohol and added that the same results were seen in the recent Glasgow epidemic.

Dr. Clouston thought valuable information would be obtained by appointing a committee to investigate the molecular change produced in the higher nerve centers. If they could make people believe that excess was harmful, good would result. Dr. Affleck considered some of Professor Fraser's dogmatic statements questionable. Pneumonia in a drunkard often ended fatally in a short time. That was due to the state of the body produced by alcohol; and yet that drug is often used in large doses in pneumonia. He had rarely seen it do any good. Its use in digestive troubles was fraught with terrible danger. The moral could not be dissociated from the medical aspect.

Dr. Ritchie quoted statistics of life insurance. These are all known to be in favor of abstinence. He found alcohol predisposed to gout and rheumatism; as to its use in cardiac failure, the heart failed about two hours after a dose and then it became necessary to give another. Dr. Foulis supported this by adding that alcohol had very little sustaining effect on the heart in chronic disease.

Dr. Leslie Mackenzie said infectious diseases were most common in children when alcohol was out of the reckoning. Cholera did not prevail in western countries where alcohol was used. Dr. Church thought in children it was difficult to decide when to give or withhold. He gave small doses, watching the effect on the pulse. Dr. C. Ker said he should be sorry to have to do without alcohol in all cases of diphtheria, almost the only cases in which he used it.

Dr. Fraser repeated his contention that alcohol was a beneficial agent, and Dr. Woodhead replied. In doing so, he said minute doses increased the susceptibility to infection; the increase of energy after a dose was of the nature of an explosion and not useful; the antipyretic effect was neutralized by the cumulative poisonous action; in diphtheria it greatly increased the liability to antitoxin rash. As to plague, Europeans were so differently circumstanced and nourished that they could not be compared with natives. Starving animals more easily succumbed to infection.

The Pathological Society had a meeting at the new laboratory of the Oxford University on the 6th inst., when Dr. James Ritchie, of Oxford, detailed some further experiments as to the relation of resistance to tetanus toxin in immunized guinea-pigs to the antitoxin value of its serum. The general conclusion reached was that a very high degree of resistance is developed early in the process of immunization while there is very little antitoxin in the blood.

Drs. W. Bulloch and J. R. Macleod related some researches they had made on the chemistry of the bacillus tuberculosis.

Dr. Bishop Harmon described the veldt and the Natal sores and illustrated his remarks with water-color drawings and microscopical specimens. Some other exhibits were also shown on this occasion.

Drs. Poynton and Alex. Paine gave an outline of their researches into the bacteriology of acute rheumatism. They have isolated from eighteen cases of rheumatic fever a minute diplococcus which maintains its virulence for a long time in media of slight acidity and also grows in media of high alkalescence. They consider the organism to be identical with that described by Triboulet, Wassermann, and Meyer. They have demonstrated it in the tissues of man and produced in rabbits the symptom-complex of rheumatic fever by intravenous inoculation of it. The arthritis thus produced varies in severity and resembles acute rheumatism in childhood rather than in adults. It begins on the third day but sometimes later—a week or more. It is a polyarthritis chiefly of the larger joints, often ending in recovery. There may result acute swelling of the fibrous tissues, causing a gelatinous appearance or a chronic fibrous thickening of the joint-capsule. The exudation may be clear, turbid, sanguineous, or fibrino-cellular. The diplococcus may be demonstrated in the exudations, but with difficulty in the most acute and in the chronic states. The organisms are destroyed by leucocytes and endothelial cells. Probably they gain access to the joints by minute capillaries in the areolar layer of the joint-capsule.

At the Obstetrical Society there has been a little discussion on spontaneous rupture of the uterus in placenta prævia, started by Dr. J. P. Maxwell, of Amoy, relating three cases, one of which ended fatally at once; the two other patients recovered after the rent was packed with antiseptic gauze. In some cases of placenta prævia, fatty degeneration of the uterine muscle has been found, and in others there seems a predisposition to rupture, though what exactly starts the accident is uncertain. Once started, the rent enlarges mechanically; Dr. Maxwell thought suture would have been fatal in a dirty Chinese home.

Dr. Champneys said that the treatment adopted was certainly the best; plugging the rent with gauze was the most successful plan when the fœtus and placenta had not escaped into the peritoneal cavity.

Dr. Herman fully supported the treatment, but took the opportunity of saying that he knew of no evidence that fatty degeneration was present in these cases, though many writers had stated it as the fact. So he had noticed some writers said the uterus in placenta prævia was soft; others said it was hard. He did not himself think there was any marked difference in consistence from that in any other pregnant uterus.

Dr. D. Robinson said he had examined two specimens of involuting uterus in woman and had failed to find the presence of fat. Dr. H. Spencer was glad to find two cases of recovery by gauze-packing; they supported the four cases he related to the society last year. Dr. Amand Routh also supported the plan; it arrested hemorrhage and secured drainage.

The President, Dr. Peter Horrocks, thought the plan the best not only "in a dirty Chinese home," but in a London or any other hospital with every appliance available. The treatment of packing was certainly the most successful, partly perhaps because the parts had not been made septic by the accoucheur's hands. He related a case of extensive rupture in which he packed, renewing the packing under chloroform every day for twelve days in succession, and afterwards less frequently. Eventually a large slough was removed from the right broad ligament. The patient recovered.

The King held an investiture of the Victorian Order, when the following were invested by His Majesty: Knight Commanders, Sir T. Smith, Surgeon-General H. J. Blanc, Mr. W. H. Bennett, Mr. T. Hansbury; Commanders, Dr. Donald Hood, Mr. J. H. Morgan, and Mr. C. A. Morris.

The death is announced of Deputy-Inspector-General Domenichetti, M.D., which occurred on the 12th inst. He served in the Indian mutiny and received the medal and clasp for Lucknow as well as the thanks of the Council. In 1895, he was appointed one of the Queen's Honorary Physicians, and in 1897 received the jubilee medal.

Deputy-Inspector-General Purchas, of the Navy, died on the 6th inst., aged seventy-six.

Dr. A. L. Wade, physician to the Somerset County Asylum, died suddenly on the 1st inst.

Inspector-General Knott, of the Navy, died on the 5th inst., aged fifty-nine.

Dr. G. H. De'ath died at Buckingham on the 7th inst. aged thirty-nine.

LONDON, July 26, 1901.

THE weather has been almost displaced by the Congress from its place as the chief topic of conversation, but it has done its best to maintain its position. The heat wave passed away at the beginning of the week quite suddenly. A drop of 14 degrees in one day arrested perspiration and grumbling at being baked. To the drop succeeded rain, and the drought is no more. Over nearly all the country welcome showers have fallen, and for days there has been unsettled weather, in some parts heavy thunder storms, in others heavy rains. By the middle of the week the temperature in many places did not reach 60 degrees. Even in London on Wednesday it was only 55, rising in the afternoon to 67 when the sun came out after a rainy morning. Yesterday an exceptionally heavy thunderstorm burst over us in London. The rainfall amounted to 1.98 inches, the bulk of which fell in an hour. Floods in various low points were the consequence. The underground railway was flooded to a depth of 4 feet near Kings Cross, and a sewer also burst into the tunnel, arresting all traffic for several hours. The hail was also severe, and some streets were for a time covered with large hailstones. Many parts of the provinces send similar reports of the weather.

The fall of temperature was most grateful to members of the Tuberculosis Congress. Had the heat wave continued

not a few would have shirked attending it. I must devote this letter almost entirely to that Congress, for it has occupied chief attention all the week. It was opened with considerable *éclat* on Monday afternoon by the Duke of Cambridge, acting on behalf of the King, who, when Prince of Wales, accepted the Presidency of the National Association for the Prevention of Consumption. As such he nominated delegates to the Berlin Congress. It was then proposed to hold a meeting here. The Prince agreed to preside, but his ascent to the throne altered the programme so far that His Majesty requested his near relative to preside in his place, taking for himself the name of patron. H. R. H. the Duke was received with great applause on taking the chair, and was supported on the right and left of the platform by the American and French Ambassadors and the ministers of several other countries as well as by representatives of our own government and societies, our colonies and foreign associations. Among these were many whose scientific reputation is world wide, such as Lister, Koch, Brouardel, and others. A very large proportion of members of the Congress were gathered in the hall, and the galleries were occupied by a brilliant assembly of ladies.

The report of the Committee, which emphasized the help afforded by the King and the foreign and Colonial Ministers having been read, the Duke of Cambridge expressed a deep interest in the subject of the Congress, a desire to assist as far as he could and his hope that good results would accrue not only for this country, but for all the world. He then declared the Congress open, and sent a telegram to the King to that effect. To this, in the course of the afternoon, His Majesty replied, thanking His Royal Highness for opening the Congress in his name, and praying him to "heartily thank for me the eminent men, belonging to almost every nation, who have assembled to-day, under your presidency, and express to them my earnest hope that the valuable information which they will give to the world, as the result of the deliberations of the British Congress on Tuberculosis, will further assist in meeting that dire disease, which has baffled the most distinguished physicians for so long." The reading of the Royal message was followed by great applause.

Lord Lansdowne welcomed the foreign delegates on behalf of the government, and referring to the prolonged war and its sorrows said no war ever waged had brought with it anything like the burden which tuberculosis from time immemorial had carried through every land. The Congress had assembled to devise measures against this enemy of the race, and he hoped its efforts would be crowned with success. Lord Cadogan, Lord Strathcona and the Lord Mayor also welcomed the Congress from their several points of view.

Lord Lister then arose, and this was a signal for most enthusiastic applause. He said thanks to Dr. Koch, who would address them on Tuesday, they now knew the enemy they had to fight. They knew, too, from Pasteur that this enemy cannot originate *de novo*, but is always derived from a similar organism. In this fact arises the hope, the splendid prospect, of prevention. But they must also seek for a cure, and as to that matters have lately become more hopeful. Every day they were learning more of our power of resisting the invasion of the microbe. The physician may learn something from the surgeon, who sometimes can sweep away the bacillus, and so restore health. The general public must help the physicians and surgeons, and he hoped the Congress might indicate the means of stamping out the scourge.

Then came the presentation of the foreign delegates to the Duke of Cambridge. They severally expressed to His Royal Highness the good wishes of their countries for the success of the Congress. There were Osler for the United States; v. Schrötter for Austria; Levi, Belgium; Gram, Denmark; Brouardel, France; v. Leyden, Germany; Thomassen, Holland; Clado, Greece; Koranyi, Hungary; Rueta, Italy; Cortezo, Spain; Holmboe, Norway; Printzjöld, Sweden; Secretan, Switzerland. Professor Brouardel said that the next Congress would be in Paris in 1903.

A vote of thanks to the Duke for presiding was heartily given, in acknowledging which His Royal Highness elicited further cheers by announcing that he understood that at the end of their labors they would find somewhere awaiting them a sum of £120,000 to enable them to carry out their scheme of a sanatorium.

In the evening there was a reception by the President and Council, at which many members of various countries contributed samples of many languages. At this Professors Woodhead and McFadyean showed lantern slides of various bacteria, bacilli, and specimens of tuberculous disease in men and animals, and mentioned how frequently meat and milk abound in the bacillus of tubercle.

On Tuesday the sections were in full work all the morning. In the afternoon came the *pièce de resistance* of the Congress—the address of Dr. Koch. This had been anticipated with no little interest; it was rumored in some circles that he would make a statement which would somewhat surprise us, but the nature of that statement was a well-kept secret. It came upon us, therefore, as almost "startling," as Lord Lister said, and others called it revolutionary. Your reporters will give you a full account of it, and here I will only stay to say that the fear expressed by the subsequent speakers seems to be generally shared. Much as we owe to Koch's discovery of the bacillus, we naturally remember also the fiasco of tuberculin, and should be reluctant to throw over the precautions which have been taken in consequence of previous researches until the new hypothesis has been subjected to the most searching investigation.

On Wednesday the Medical and Pathological Sections met together to discuss tuberculin, which they did at considerable length, nineteen or twenty gentlemen speaking in the debate, which was opened by Dr. Heron, who was followed by Koch. It was instructive to note how all seemed agreed upon certain important points. All were satisfied that the diagnostic value of tuberculin was very great and all agreed that the doses must be very small. But as to treatment, the great majority were unconvinced, and the danger of using it in febrile cases was emphasized. Koch himself admitted it was not suitable in such patients, who, he said, should be put to bed and the fever reduced before employing it. But as Sir D. Powell and others pointed out, most cases in practice are febrile.

In the afternoon at the general meeting, Professor Brouardel delivered his address. Of course, it was prepared before Koch's statement was made, and showed that his views were directly opposed to those of the German savant. In fact, he fully adopted the generally received doctrine. He is an optimist as to treatment and preventive measures. He dismissed the old opinion of hereditary influence in the neat aphorism: "*On ne nait pas tuberculeux mais tuberculisable.*"

Mr. Chaplin, who presided, remarked that if Dr. Koch's views should be confirmed they would answer a question he sometimes put to his late excellent colleague Sir R. Thorne: "Thorne, if all the dreadful things we are told about the transmission of tuberculous disease by meat and milk are true, how is it that any of us are left alive?"

In the evening the banquet to Koch at the Royal Institute of Public Health was attended by a number of distinguished guests. General Gatacre, in reply to the toast of the Services put in a good word for the medical department, and pleaded that the government should provide the best appliances and the opportunity for study if they wanted the best professional work. Sir H. Harben replying for the Houses of Parliament said he would give a £50 medal for the discovery of a microbe which would destroy the consumption of time in the House of Commons. Sir J. Crichton-Browne thought that another Commission should enquire into the subject. If the Government appointed one he announced that Sir James Blyth would place at its disposal his model farm. Of course, the most interesting personality was the chief guest. The manner of his reply was excellent, and when asked after speaking in German to say something in English, he repeated his thanks for the honor accorded him in our language. It was interesting to watch the manner in which he phrased his thanks in the two languages.

Yesterday afternoon the King received the foreign delegates to the Congress in the Throne Room. The Earl of Derby presented them, and His Majesty shook hands with each. When all had grouped themselves about him, the King addressed them. He said he was sorry that they arrived in such a severe thunderstorm, and that it was a matter of concern to him that circumstances over which he had no control prevented him from opening the Congress. He hoped their labors might minimize the effects of the disease, and so they might receive the gratitude of the world. Then he added, there is another "terrible disease which up to now has baffled the scientific and medical men of the world, and that is cancer. God grant that before long you may be able to find a cure for it or check its course, and I think that to him who makes the discovery a statue should be erected in all the capitals of the world. In taking leave of you I trust that your stay in London and in England has been an enjoyable one, and that you will one and all carry away pleasant recollections of your visit to my country."

Syphilitic Epilepsy.—G. Salomone reports a case in which a neuropathic family history could be excluded. The patient contracted syphilis in 1899, and his first epileptiform attack was preceded by a series of symptoms which indicated a cerebral syphilitic localization, such as nocturnal headache, roaring in the ears, difficulty in hearing, high temperature, and slight asymmetry of the face. Mixed treatment resulted in a cure, and the epileptiform attack did not return.—*Annali di Medicina navale.*

Progress of Medical Science.

The New York Medical Journal, August 3, 1901.

Spiculum of Bone from Shot Fracture of Skull which Rested against the Brain for Forty-four Years.—D. S. Lamb gives a picture of an irregular piece of bone, one and a half inches by five-eighths of an inch in diameter, which was removed, post-mortem, from the pial bodies, where it was imbedded. The patient had been shot in 1857. Neither bullet nor probe had been followed by symptoms of injury.

"Inoperable" Recurrent Cancer of the Breast; Relief by Beatson's Method.—Robert Abbe reports two cases in which oöphorectomy caused a disappearance of the malignant growth. Beatson holds that so-called special cancer-cells will be found to be vacuolated germinal cells corresponding with those found in the ovary alone. Special cancer growth seems to be due to epithelium taking on characteristics of germinal epithelium; the distinguishing cells are not normal epithelium, for they act differently. Beatson thinks ovarian influence works this change in the active processes of mammary cancer, in which the epithelium takes on the characteristics of germinal epithelium. The author, in addition to his two positively successful cases, has five others which are as yet too recent for a report. Whether or not one accepts Beatson's view of the cause of the disappearance of cancer nodules and masses in some patients following simple oöphorectomy, the fact remains to be explained by the pathologist.

Cancer, Particularly Cutaneous Cancer.—Ellice M. Alger holds that if traumatism is not an essential, it is often an exciting, cause in cancer of the skin. He thinks that many facts are decidedly opposed to the germ theory. It is interesting to note that cancer attacks the strong and spares the weak. Ulcer of the leg is said to be very rare in cancer patients, and the converse is also true, that patients with ulcer rarely have cancer. The same may be said of syphilis and tuberculosis. The treatment of cutaneous cancer requires great judgment. No internal medication has, so far, proved of any value. A partial operation may be worse for the patient than non-interference. Superficial epitheliomata and those occurring in the very old are commonly of indolent growth. On the other hand, growths in the vicinity of lymphatics should be removed at the earliest possible moment. Arsenic may be used when operation is not consented to, or when there is no lymphatic involvement.

Flagellated Malarial Parasite.—John T. Moore states that his observations show that the flagella are preformed in the body of the organism, which is in opposition to a statement by Marchiafava and Bignami. He is convinced by what he has seen that these flagella are fertilizing elements, coming from the hyaline ovoid bodies, that pass to the granular forms to prepare them for further development in the mosquito cycle, as taught by the best observers. His observations have led him to doubt the teaching concerning the origin of the flagella, or microgametes. The drawings he has seen of both fresh and stained specimens seem to show the flagellum as a pseudopod-like process coming from the periphery of the body, and having the same structure as the protoplasm of the parasite itself. He has seen the granular bodies in both the tertian and estivo-autumnal pigment-containing parasites all at once set in commotion as if something very active were on the inside trying to get out. In a short time a projection would be seen, and a little later out would come a thin, hyaline, filamentous body. Careful focusing convinced him that one-half of the flagellum could be seen within the parasite

Medical News, August 3, 1901.

The State of the Gastric Secretions in Chronic Rheumatism and Rheumatoid Arthritis.—Frank H. Murdoch reports five cases of rheumatism and one of rheumatoid arthritis in which repeated examinations of the gastric contents showed the secretion to be abnormal. The treatment in these cases was directed against the existing dyspepsia, not against the joint affections, with recovery in every instance. The author believes that in chronic rheumatism and rheumatoid arthritis the diet prescribed should in each case suit the existing state of the gastric secretions.

Ulcer of the Duodenum Considered from a Surgical Standpoint.—D. S. Fairchild believes that if a non-perforating duodenal ulcer can be diagnosed, an operation is indicated before grave symptoms supervene. In perforating ulcer the importance of early operation, within twenty-four hours, is very great. The only operation for non-perforating ulcer is gastroenterostomy. He considers positive diagnosis in cases of non-perforating ulcer to be comparatively easy if there is present pain in the right hypochondrium two to four hours after meals, unrelieved by vomiting, and bloody stools.

Injuries of the Head in the New-born.—Andrew F. Currier considers that the possibilities of injuring the child's head by the use of forceps in delivery should be more cogently expressed by writers on obstetrics. Injuries received in the course of natural or assisted labor may result in immediate death, death a few months later, recovery, or, most important, recovery with permanent lesion such as renders parts of the body useless or ineffective. To the latter class belong imbecility, idiocy, some facial deformities, and the various birth palsies. He considers that treatment of such injuries should be instituted within the first few days of life and should be on the same lines as would be pursued in similar cases in later life. He gives statistics of sixty cases in which the skull was injured in the process of birth.

Journal of the Am. Med. Association, August 3, 1901.

A Note on the Use of Thuja Occidentalis in Removal of Papilloma of the Larynx.—James Moreau Brown reports a case in which the application of thuja caused such shrinking of the growth after partial removal by operation, that further operation was abandoned, and the thuja only applied, with the result of complete disappearance of the growth. In addition, the author knows of several cases of a recurrent type in which the growths have entirely disappeared under the use of thuja with no evidence of recurrence after several years.

The Diagnosis of Mild and Irregular Smallpox as Found in the Present Outbreak in the United States.—Heman Spalding says that in about twenty-seven months, three hundred and ten cases of smallpox have been found in Chicago. Some of the cases were typical, but the greatest number were deviations. There was one hemorrhagic case resulting in death, thirteen confluent, with three deaths; twenty-four semi-confluent, with two deaths; fifty-four severe discrete cases with no deaths; one hundred and seventy-nine mild discrete cases, no deaths; thirty-nine modified form—cases in which there was evidence of a more or less successful vaccination, with no deaths. Of these three hundred and ten cases, two hundred and seventy-one never had been successfully vaccinated. Of the others the most recent vaccination was sixteen years previous to the attack. The author gives the differential diagnosis between smallpox and chicken-pox.

Acute Mastoiditis After Subsidence and Without Recurrence of Tympanic Inflammation.—Hiram Woods, Jr., reports three cases in which after otorrhœa ceased, acute mastoid symptoms developed. The question, when did the mastoids become infected, is of interest. In one of the cases there was no symptom of mastoiditis until twelve days after tympanic disease had disappeared. Of the other two, one had neck rigidity throughout, and the other had rigidity at first, with sudden cessation of otorrhœa and simultaneous mastoid pain, disappearing in two days and never returning. Cold was used in treatment, and in two of the cases with apparent benefit. Yet the author is inclined to agree with Dr. J. O. Janeway, that cold merely masks symptoms, while it increases the trouble from hemorrhage and the difficulty in distinguishing healthy from diseased bone during operation and slow recovery. It is impossible to secure a sufficient amount of cold to kill organisms in the mastoid.

The Boston Medical and Surgical Journal, August 1, 1901.

Practical Blood Examination.—Henry F. Hewes states that the scope of practical blood examination at present, is to determine the existence or non-existence of anæmia, its severity and type, leucocytosis, its extent and type, the presence or absence of blood parasites, the existence of definite serum reactions in the blood, and the presence of bacterial organisms—that is, septicæmia. Barring the tests for bacterial infection, the determination of septicæmia, and the serum reactions, the whole scheme of practical blood examination may be accomplished by the employment of two very simple methods of examination: 1, the estimation of the hemoglobin, and 2, the examination of a stained specimen of blood. The author describes the processes in detail and says that his object is to impress upon practitioners the extreme simplicity of the work, in the hope that this examination may be more commonly used in general practice.

Rachitic Deformities of the Spine.—J. S. Stone says that the usual spinal deformity in rickets is a general kyphosis extending from the lower cervical region downward, and most marked in the lumbar region. Lateral

deviation is more rare. In older rachitic children there is at times a greatly increased lumbar lordosis. Muscular weakness is the essential factor in the causation of these deformities. Diagnosis is easy, but differentiation from Pott's disease may be difficult, because the lumbar rachitic kyphosis due to rickets sometimes does not disappear on recumbency, and there may be marked rigidity on attempted extension of the spine. The treatment of both is identical, and should consist in recumbency upon some firm, even surface. If due to rickets alone the kyphosis will disappear with reasonable promptness. There should also be general tonic treatment with rubbing and massage. Outdoor air and sunshine and a diet rich in proteids and fats are necessary. If properly treated, recovery from rachitic deformity of the spine is usually complete.

Philadelphia Medical Journal, August 3, 1901.

The Mosquito an Insignificant Factor in the Propagation of Yellow Fever.—John H. Purnell considers the theory of transmission of yellow fever infection by the mosquito untenable, and endeavors to support his conclusion by presentation of numerous facts, not the result of direct experimental research, but the result of observations of men working in the yellow-fever field. In the epidemics of the disease which have of late years been successfully controlled, in no known instance have the measures employed been directed against the mosquito. He thinks the fomites theory demands careful consideration before being discarded by the profession.

Typhoid Fever Occurring in a Tuberculous Patient, and the Influence of Tuberculin on this Condition.—Erwin Fischer reports the case of a patient who developed typhoid fever while suffering from tuberculosis; he recovered from the fever, and the tuberculous condition improved. The tuberculous condition had been treated by tuberculin since its onset. The family history and the condition of the patient at the time of onset of the fever were such as to indicate a fatal termination. The author considers the improvement due to the immunization which was the result of the previous use of tuberculin, and advocates the use of the latter for treatment as well as for diagnosis.

Human and Bovine Tuberculosis.—Leonard Pearson states that the relation between human and bovine tubercle has been more studied in this country than in any other. Much experimental work has been done on carnivora and herbivora of both the resistant and non-resistant species, and the bovine tubercle bacillus has been constantly proven more virulent for animals than has the bacillus from man. The number of accidental cases of tuberculosis contracted by men handling tuberculous cattle shows that bovine tubercle bacilli may, under some conditions, be virulent for man. From this he concludes that further study of the relationship between human and bovine tuberculosis is necessary; in the meantime, efforts to repress the disease in cattle must be continued.

American Medicine, August 3, 1901.

Important Sequels Resulting from Delayed Operation in Appendicitis.—A. Stewart Lobingier concludes, from a review of the literature of appendicitis and his own experience, that there can be little doubt that many of the cases of appendicitis reported cured are only partially so and that many grave conditions follow appendicitis which might have been obviated by early operation. The probability and gravity of the sequelæ are often lost sight of, the problem usually presented being simply whether the operation will result in immediate recovery or death. While this is certainly of primary importance, the question of speedy dissemination of the pyogenic germs to structures whose injury means permanent physical wreck of the patient should not be overlooked. The sequels of the disease are universally recognized as constituting the most formidable class of surgical cases and are to be avoided by early diagnosis and operation.

Report of a Case of Hysteroepilepsy, in Which the Climax of the Seizure was Expressed by Discharge of Blood Through the Intact External Auditory Canal.—K. K. Wheelock reports in detail the case of a woman, aged twenty-eight, married, who two years prior to the birth of her last child, in 1896, was subjected to fainting spells with clonic spasm and frothing at the mouth during her menstrual periods. The spasms ceased with the birth of the child, but she has since had discharges of blood from both ears at irregular intervals. The hemorrhages are preceded by dizziness, mastoid pain, and frontal headache. Examination showed the external auditory canal and drum membrane of both ears to be intact. Hydriodic acid and potassium bromide were prescribed. The patient was in the second month of pregnancy, she was entirely free from spasms, and there was an interval of three months without aural discharges. A year later the discharges became more frequent, being worse during menstruation, and the spasms reappeared, without loss of consciousness this time. The observations extended over a period of about two years.

French Journals.

Congenital Diaphragmatic Hernia.—Porak and Durante describe a fœtus with this affection, the diagnosis of which had been made during life. The left half of the diaphragm was not developed. The liver was higher than normal, its left lobe extending into the thorax.—*Gazette Hebdomadaire de Médecine et de Chirurgie, June 6, 1901.*

Sarcoma of the Heart Secondary to Sarcoma of the Kidney.—Rabé and L. Morel report a case of sarcoma of the heart secondary to sarcoma of the kidney. As a result of metastasis, there was formed over the anterior surface of the heart a nodular mass about the size of a pigeon's egg. This nodule involved the entire thickness of the wall and extended into the cavity of the right ventricle. There were four or five secondary foci in the lungs. The sarcoma was of the small spindle-celled variety.—*Gazette Hebdomadaire de Médecine et de Chirurgie, July 18, 1901.*

Intestinal Occlusion by Biliary Calculus; Expulsion of the Calculus by Oil Enemata.—Widal Mourette reports the case of a woman, sixty-six years old, who, never having had hepatic colic nor jaundice, felt a sudden pain in the right hypochondrium near the umbilicus. This was followed by vomiting, first biliary, then stercoraceous, showing complete intestinal obstruction. Before an operation was undertaken, it was decided to attempt to clear the intestine by voluminous enemata of sterile olive oil. The second enema caused the expulsion of a biliary calculus as large as a hen's egg. Recovery was uneventful. In the presence of intestinal obstruction of unknown cause, it is wise to think of the possibility of occlusion by a calculus developed in the course of biliary lithiasis which has, up to this time, been latent, and if there is time, it is advisable to attempt measures to clear the intestine.—*Gazette Hebdomadaire de Médecine et de Chirurgie, June 27, 1901.*

Calculus of the Gall Bladder; Muco-Purulent Fistula of the Bladder.—G. Alexander reports the case of a woman thirty-three years old, who, in August, 1900, in the course of pregnancy, was taken with chill, fever, rapid pulse, etc. She was prematurely delivered at the sixth month. Twelve hours later she was operated on for the calculus. The operation consisted of extraction of a calculus followed by cholecystostomy. A fistula resulted from which flowed a clear mucus, which later became purulent. On exploration with a probe, a calculus was felt which could not be moved. A second operation was undertaken the following April. The fistula was circumscribed by an elliptical incision, the calculus was detached from the inferior surface of the liver, all adhesions were broken, and the biliary ducts were explored. The gall bladder alone contained a large calculus, which had torn the bladder wall by one of its sharp edges. There was a depression in the wall of the bladder, into which the calculus fitted, thus accounting for the immobility of the stone. The persistence of the fistula was due to the continued presence of the calculus whose conformation and situation prevented its discharge with the bile through the fistula.—*Bulletins et Mémoirs de la Société Anatomique de Paris, April, 1901.*

The Journal of Tropical Medicine, July 1, 1901.

Portable Folding Mosquito Net.—P. Carmody presents the sketch of a mosquito net designed for the use of travelers in the tropics. It is either attached or attachable to the ordinary linen umbrella, which forms a part of every tropical outfit, and the combintion affords protection from the sun during the day and from mosquitos during the night.

Prickly Heat.—Frederick Pearce explains to readers of a former article that he did not say that soap can produce an acute seborrhœa. He does consider soap injurious to the skin by removing its natural grease, and deprecates its use, especially in the tropics. He finds his recommendation to oil the skin in prickly heat very successful, and prefers lanolin in almond oil, with the addition of a little menthol. He considers prickly heat to be a form of acute seborrhœa, but whether any bacterial or fungous growth is the proximate cause he has not been able to determine.

Goundou Preceding Chronic Hydrocephalus in a Malay Child.—Lim Boon Keng reports the case of an infant of six months suffering from symmetrical swellings on each side of the bridge of the nose. Beneath the skin there was practically the growth of bone tissue, with large

cavities possessing very thin walls. The most prominent parts of the goundou masses were soft, and a slight pulsation could be detected which moved synchronously with the fontanelles. The author came to the conclusion that the bone cavities contained prolongations of the cerebral meninges, and that the pulsation took place through the intervention of the cerebrospinal fluid. Nearly two years later the child was brought back suffering from chronic hydrocephalus, from which it died.

Does Malta Fever Exist in Havana?—Emilio Martinez reports three cases which clinically exactly resemble undulant fever. In the first case there were long waves lasting ninety-eight days The second case lasted 114 days, and had four undulations. The third case had eight months of fever with three waves and one that was incomplete. The prolonged duration was another characteristic of Malta fever, and a further resemblance was found in its benignity. Articular localizations were also found. The malignant type of the disease was also present. The author says that blood examinations should be made to prove by the positive serum reaction of the micrococcus melitensis, whether undulant fever is prevalent in Cuba or not.

On Hemorrhagic Bulla of the Mouth and Pharynx.—J. Preston Maxwell says that in the whole region of Fokien, Southern China, there exists a curious disease, consisting of a large bulla in the mouth which bursts and discharges dark blood. The pathology is obscure The Chinese universally attribute it to the web of a peculiar fly-catching spider In several instances patients have affirmed that they saw the spider jump out from their basin of condiments, and, taking a piece from that place, have been immediately victimized. Unfortunately, the efforts of the writer to reproduce the condition artificially in animals and man has been a failure. The affection may come on while eating rice, sugar, soft biscuits, drinking tea, or merely lounging about. The prognosis is good, and the treatment is simple, as a tannic acid gargle quickly stops the bleeding.

A Sporadic Case of Beriberi with Blood in the Urine.—A. B. Dalgetty describes what seems to have been an isolated case in South Sylhet, India. The patient was a man of twenty-seven, a native of the district, who had never been far from home, and lived, like his neighbors, on meat, rice, fish, peas, and the like. His family lived near, used the same drinking water and the same rice, and lived otherwise exactly as he did, but he was the only one to have fallen victim to beriberi. The symptoms of the disease were well marked. Three months of a treatment consisting in malt, cod-liver oil, strychnine, digitalis, quinine, bitters, etc., caused a great improvement, sensation having returned to the dull areas, although the muscles still remained weak. The urine contained a trace of albumin and a considerable number of xanthocytes as well as different forms of epithelium.

Annals of Surgery, July, 1901.

Aneurism of the Thoracic Aorta of Traumatic Origin, Treated by Introduction of Wire and Electricity.—By De F. Willard. The patient was a man of twenty-three. A heavy box, weighing five hundred or six hundred pounds, fell upon his chest. After six weeks' rest he resumed work but became more and more troubled by cough and chest pains, and in six months was obliged to lie up. A diagnosis was made of some traumatic lesion of the descending thoracic aorta. The wire was introduced through a trocar inserted in the fourth interspace just outside the costal cartilage, silver wire No. 24 being used. After some six or eight feet were in the sac, the current was turned on, the positive pole being attached to the wire and the negative to a flat electrode between the scapulæ Subsequently more wire was passed. The immediate effects of the operation were excellent, but the case is still under observation, and some of the original symptoms have returned. Nine weeks after the operation, however, the patient felt so well that he refused to remain longer in the hospital and went home against the author's protest. The latter proposes to repeat the operation.

Two Cases of Ligation of the External Carotid for Severe Hemorrhage—One after Tonsillotomy, the Other after a Slight Intranasal Operation.—W. W. Keen says that to ligate the common carotid when the bleeding vessel is a branch of the external carotid is an inexcusable surgical blunder. Not infrequently the cutting off of the brain circulation through the internal carotid has resulted in cerebral softening and death. In neither of his cases did the operation wound bleed Case 1 was that of a man of twenty-three whose left tonsil was removed early one forenoon. There was no special hemorrhage at the time but the bleeding could not be checked. Cold water, hot water, pressure, packing, styptics, etc., all were used but to no avail. Dr. Keen operated six hours later, the patient having lost three pints (estimated) of blood. Recovery after the operation was uneventful and the patient left for home on the ninth day. A tonsillotome was used for the primary operation. Case II was that of a man who had had hypertrophies removed with a curette from the posterior part of the septum. The bleeding recurred at intervals for several days and the artery was finally ligated on the nineteenth day after the first curetting. Recovery was uneventful,

The Mortality of Operation for Obstructive Jaundice.—J. B. Deaver reports five cases and presents various statistics. He advises early operation not only in the acute exacerbation of the condition, but in the early days of the condition itself. He says that the most common cause and more common than all the others put together, is obstruction from gall-stones. Parasites are so rare that they can be passed by with mere mention, although the indication here is distinctly surgical. Every case of cholelithiasis that he has operated upon has given a history of repeated attacks treated medically, yet has not been cured of the disease or freed from its dangers. Each succeeding attack is accompanied by local and systemic changes, which detract from a favorable surgical prognosis. The most common cause of death is hemorrhage, caused by changes in the blood; the next most common is exhaustion, or what the author believes to be cholæmia, and third, most common, shock which is a result of hemorrhage; and these three causes are undoubtedly enhanced by delay or long continuance of the pathological factors of the disease. It would seem, then, that operation, and early operation, offers the best safeguard to the evil possibilities of obstructive jaundice due to cholelithiasis.

Report of a Case of Recovery from Perforating Typhoid Ulcer of the Intestine after Operation.—W. Jones reports the case of a young woman of twenty, in whom the accident happened during the fifth week of the disease. On opening the abdomen, the perforation was searched for but not found. The condition was one of general diffuse purulent peritonitis. The patient stood the operation well. On the second day there was a free discharge of fæcal matter through the tubes, which had been left in the median incision, but the fæcal discharge lessened and ceased at the end of a week, though returning again later. Finally the fæcal fistula closed spontaneously and completely. The patient made a complete recovery. In this case the search for the perforation was deliberately abandoned when it was not readily found; the patient's condition would not permit of prolonged anæsthesia nor of much manipulation of the intestines. The indications were to give free vent to the septic fluids and limit the extension of the septic area. The discharge of fæcal matter through the infected area and the external wound would not add materially to the quantity or virulence of septic absorption. The closure of the perforation would not have added greatly to the prospect of the patient living, while a prolonged search would have been almost certainly fatal.

Wounds of the Venous Sinuses of the Brain: an Analysis of Seventy Cases.—From a study of the cases enumerated, H. R. Wharton draws the following conclusions: (1) Wounds of the venous sinuses of the brain should be classed as dangerous injuries, being followed by a high mortality from external or intracranial hemorrhage or septic infection. (2) They are especially liable to infection, resulting in septic thrombus and pyæmia, therefore the greatest care should be taken to render them aseptic and preserve them in that condition. (3) The most satisfactory and generally available method of treatment consists in controlling the bleeding by aseptic gauze packing. (4) Ligation of the venous sinuses presents definite dangers in itself, is only available in certain wounds where a free exposure of the injured sinus is possible, and cannot be employed with advantage in ordinary accidental wounds of the sinuses. (5) The application of a lateral ligature to a wound of a sinus is less difficult and dangerous than ligature of the sinus, but is applicable only to small wounds. (6) Suture of sinus wounds is a valuable procedure in a certain class of cases, namely, small wounds which can be freely exposed. (7) Forceps pressure is also a ready method of controlling hemorrhage from wounds of the sinuses, but possesses no distinct advantages over some of the other methods, and its employment is accompanied by certain dangers.

Fractures of the Neck of the Femur.—John Ridlon reviews the various methods of treatment and recapitulates the general principles as follows: Stimson says, "the first consideration is to keep the patient alive; the

second to obtain union; the third to get union in a good position." Ridlon cannot fully agree with this. He would not make it the first consideration to keep alive a patient of threescore and ten years if she must be bedridden or a helpless cripple for all the rest of her life. Indeed, a woman of eighty may live ten years, and a younger woman had better be dead than a helpless cripple for ten years. Further, the occasion of death in a large percentage of cases is not the shock of the accident, nor the shock from the replacement of the fragments, nor the confinement in bed, but it is the pain and suffering resulting from irrational treatment. It appears to him that the first consideration should be to relieve the patient from suffering. This can best be done by replacing the fragments as completely as possible, and retaining them by the best possible fixation. If the patient can possibly live, she will live when freed from pain. The second consideration should be to use such an immobilizing dressing as will least irritate the patient, as will make it possible to keep the skin clean and dry, and free from pressure-sores; such a one as will permit the use of the bedpan and the turning of the patient in bed without pain, for pain means movement of the fragments one on the other. The third consideration should be to continue immobilization of the fracture and protection from all sensitiveness. Fourth, the treatment of the hip should be continued until the joint is sound as well as the fracture united.

Bulletin of the Johns Hopkins Hospital. July, 1901.

A Case of Arterial Disease, Possibly Periarteritis Nodosa.—Florence R. Sabin reports a case, without autopsy, whose clinical features corresponded with those of the four recorded cases of periarteritis nodosa which were proved by autopsy. The lesions of the disease were nodules on the arteries. The blood count showed a pure leucocytosis of high grade, pointing to the inflammatory nature of the disease. The author considers the clinical picture sufficient, with the presence of nodules, to justify the diagnosis.

Typhoid Infection Without Lesion of the Intestine; A Case of Hemorrhagic Typhoid Fever with Atypical Intestinal Lesions.—Eugene L. Opie presents in detail, with autopsy, a case resembling those reported as typhoid fever without intestinal lesions. He believes that typhoid fever without intestinal lesion is a possible occurrence, but thinks the evidence furnished is inconclusive. In his own case minute study revealed only slight changes present in Peyer's patches and the solitary follicles of the small intestine, with points of pigmentation in the solitary follicles of the large intestine; the clinical history indicated intestinal involvement early in the disease. Cases in which death occurs in the early stages will furnish the only conclusive evidence that intestinal lesions have not been present in cases in which typhoid fever has been positively diagnosed. Analysis of a number of the cases reported does not support the assumption that the typhoid bacillus can enter the body by any path other than the digestive tract.

Ovarian Organotherapy.—William Krusen states his experience for the past three years in the use of ovarian extract for cases suffering from amenorrhœa, dysmenorrhœa, and other pelvic disease, for those suffering from symptoms following the removal of the uterine appendages, and for disturbances associated with the menopause. He concludes; (1) That the ovarian extract is practically harmless. (2) No good results are obtained in the treatment of amenorrhœa and dysmenorrhœa. (3) The best results are obtained in the relief of artificial menopause. (4) No appreciable results follow its use in the natural menopause. (5) No definite reliance can be placed upon the drug. (6) It is doubtful in those cases where relief was noted, whether this was not due to mental suggestion. (7) Increase in dosage seems to have little influence in maintaining the effect of the drug or in preventing the patient from becoming accustomed to it. (8) The theory of the use of this extract seems to be faulty, and the administration of ovarian extract is based upon a wrong assumption as to the function of the organ. If coincidently with ovulation any peculiar product is formed it has not yet been isolated.

Ulcer of the Stomach Caused by the Diphtheria Bacillus.—William R. Stokes believes that in cases of widespread diphtheria, when the gastric juice is lessened in quantity, the large numbers of diphtheria bacilli swallowed are apt to cause local lesion of the gastric mucous membrane. He cites a case with fatal termination, in which the patient had complained of pain and hyperæsthesia in the epigastric region. The patient, a young man, was found in the street and it was impossible to ascertain the duration of the disease. Cultures from the throat taken on two occasions showed the bacilli. The antitoxin treatment was employed and on the sixth day the temperature, which had been high, fell and the membrane had almost disappeared from the throat. Death occurred ten days after treatment was instituted. Post-mortem examination revealed an ulcer in the most dependent portion of the greater curvature of the stomach, near the pylorus. This ulcer consisted of a mass of coagulative necrosis extending into the submucosa and undermining the mucosa laterally. Bacteriological examination showed the diphtheria bacilli to be limited to the necrotic material, much more numerous on the surface. The author believes that stomach lesions produced by the diphtheria bacilli will, in time, be found to be more frequent than has been heretofore supposed.

Archives of Pediatrics, July, 1901.

Hemorrhage from a Pyothorax.—A. Jacobi reports the case of a child of seven years who was operated on for pyothorax, about 500 cm. of white, inoffensive pus flowing from the opening. Thiersch's solution was injected, and returned with a little more pus which was slightly colored with blood. All at once, a large amount of undiluted blood was discharged. Altogether at least 250 c.c. of blood were lost. The blood was seen oozing from tufts disseminated over the pulmonary pleura, the costal not being within view. The intercostal artery was not touched. No malignant tumor was found; there was no suspicion of tuberculosis, or of maceration and corrosion of the surface, and there was no adhesion between the pleuræ, the tearing of which might have given rise to hemorrhage. The child made a good recovery. The case is unique. The pleural abscess behaved similarly to abscesses situated in looser tissues elsewhere, in which granulating tufts spring up from the suface with occasionally a moderate tendency to bleed.

Report of Two Cases of Tuberculosis of the Hip and Spine, Treated with Large Doses of Creosote.—Agnes Walker reports two cases of interest on account of the large amount of creosote administered without producing injurious or unpleasant results. The first case was a boy of three years, who, in December, 1893, was put upon 1-minim doses of a ten per cent. solution. This was gradually increased until, in November, 1895, he was getting a daily amount of 371 minims, with no apparent effect for good or evil. Treatment was discontinued. The second patient, a girl of seven years, received the creosote solution for four months, the dosage having by that time reached 300 minims of the solution, or 36 minims of pure creosote daily. She left the hospital in excellent condition, and from having been confined to bed, wearing spinal traction apparatus, is now able to walk, run and bicycle. No evidence of renal disturbance was found in either case.

The Differential Diagnosis of Ectopic Pregnancy.—(1) The frequency with which ectopic gestation is diagnosticated as early uterine abortion. (2) The advisability of looking with suspicion upon every case presenting apparently the symptoms of early uterine abortion, and if the case is not running a simple and natural course, to fully anesthetize the patient for a rigid examination and for the proper performance of curettage in the event of uterine abortion being present. (3) If after carrying out this plan there still be some doubt, the advisibility of making a posterior vaginal exploratory incision to determine the presence or absence of blood in the pertioneal cavity and to be prepared to open the abdomen if the condition found calls for it. (4) The unreliability of the so-called pathognomonic signs or symptoms of ectopic gestation.—Hiram N. Vineberg, *Journal of the American Medical Association.*

A Report of the Nasal Septum as Found in the Skulls of Forty Mound-Builders.—George B. Wood reports from his study of these skulls that a perfectly straight condition of the bony part of the septum existed in only thirty-two and one-half per cent.; and this does not exclude any possible deviation of the cartilage which might have existed during life. The lesser deviations and spurs would raise this percentage up to sixty-two and one-half. These results closely resemble Price-Brown's, where fifty per cent. of the septums were deviated and fifty per cent. straight; but scarcely do they warrant Lennox Browne's assertion that in the aborigines of Africa, America, and Australia there is one asymmetrical to every four symmetrical. The writer has reported these septums to furnish one small item of statistical information which may be used in the endeavor to settle the question of etiology of septal deformity. He believes these results tend to disprove the theory that the commixture of races is accountable for the great majority of those septal deformities which develop during the growth of the child.—*Univ. of Penna. Medical Bulletin*, July, 1901.

Society Reports.

THE BRITISH CONGRESS ON TUBERCULOSIS.

Held in London, July 22-26, 1901.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

First Day—Monday, July 22.

THE British Congress on Tuberculosis was opened at St. James's Hall, on July 21, by H. R. H. the Duke of Cambridge, at the request of the King. The opening session gave promise that this would be one of the most successful of medical congresses and one likely to lead to as important practical results in the prevention of disease as any other ever held. The number of members was over 2,000, including representatives from every country in the civilized world. The gathering at St. James's Hall was large and enthusiastic. On the platform were diplomatic and medical representatives of nearly every civilized government and the British colonies, delegates from medical societies of every country, representatives of corporations, and of town and borough councils of the United Kingdom, and eminent medical men of all nations. Amongst them were the American and French Ambassadors, the Greek, Swedish, Portuguese, Netherland, Danish, Servian, Roumanian, and Peruvian ministers, the presidents of the Colleges of Physicians and of Surgeons of London, Edinburgh, Glasgow, and Dublin, and many British and foreign practitioners of note.

The DUKE OF CAMBRIDGE said that, at request of the King—who, when Prince of Wales, intended to open the Congress himself, but was debarred from doing so by his accession to the crown—he had great pleasure in performing the duty. The subject which brought them together was one which would have good results for all countries. He welcomed the foreign delegates whom he was glad to see in such large numbers. A telegram was forwarded to the King informing him of the opening of the Congress, and a reply was received from His Majesty, wishing the Congress every success.

Mr. MALCOLM MORRIS, the Honorary Secretary-General, read his report. He said that the movement originated at the German Congress on Tuberculosis, held in Berlin in 1899, when representations were made to the British delegates as to the desirability of a congress in London, and the latter reported the matter to the National Association for the Prevention of Consumption. This body took the necessary steps, sending out over 3,000 invitations to the principal medical, sanitary, educational, and agricultural institutions in the United Kingdom. Lord Lansdowne forwarded letters of invitation to the foreign governments, and the Colonial Secretary to all the colonies of the Empire. It was resolved to divide the work of the Congress into four sections, viz., (1) State and Municipal, (2) Medical, (3) Pathological, and (4) Veterinary. A museum had been established which contained specimens of every known form of tuberculosis in man and animals, plans and models of hospitals and sanatoria, and charts and documents bearing upon the historical, geographical, and statistical aspects of the question.

Lord LANSDOWNE, Foreign Secretary, said that the government would give every facility for the work of the Congress, and fully realized the immense importance of the subject. The country was suffering from a prolonged war which brought sorrow to many a household; but no war ever waged brought such dire results as tuberculosis. An immense debt was due to those who showed that it was not incurable.

Earl CADOGAN, Lord Lieutentant of Ireland, speaking on behalf of that country, said that tuberculosis was a great scourge in Ireland, and that in the mortality statistics the returns of deaths from that disease were higher than from any other cause except old age.

Lord LISTER said that the Congress met under immensely better auspices than were formerly possible. Thanks to Koch, we now know the enemy we have to fight. Previously the cause of tuberculosis was shrouded in obscurity. Thanks to Pasteur, we know that the bacilli cannot originate *de novo* in the human body. Hence the possibility of prevention. Cure was also possible, and more to be hoped for now than formerly. In surgical tuberculosis, if irritation of the part was scrupulously avoided and the general health improved, the bacillus would be swept away and the part become healthy again.

Dr. WILLIAM OSLER, of Baltimore, said that not for many years had such a delegation of American physicians crossed the Atlantic as had come to this Congress. They did not come like the "trusts" of which so much was heard of late, yet they represented a magnificent "trust." The work of prevention was being pushed in the United States. They had to perform the work of educating the members of the medical profession—who needed education on this point badly—and of educating the public, who needed it more. Bunyan, in the "Pilgrim's Progress," had spoken of the "Captaincy of Consumption" in the army of death; that captaincy had now been reduced to a lieutenancy, and was on the way to a further reduction to the ranks.

The following foreign delegates also spoke on behalf of their respective governments, wishing the Congress every success: Prof. von Schrötter (Austria), Senator Montefiore Levi (Belgium), Prof. Gram (Denmark), Prof. Brouardel (France), Prof. von Leyden (Germany), Prof. Thomassen (Holland), Prof. Koranyi (Hungary), Senator Di Rienzi (Italy).

Second Day—Tuesday, July 23d.

The Combating of Tuberculosis in the Light of the Experience that Has Been Gained in the Successful Combating of Other Infectious Diseases.—Professor ROBERT KOCH, of Berlin, delivered an address with this title. He said that in the majority of cases of tuberculosis the disease had its seat in the lungs and began there. The sputum of consumptive people was the main source of infection. Hereditary tuberculosis, though possible, was extremely rare, and might be disregarded in considering practical measures. It was generally assumed that tuberculosis was transmitted from animals to man, but the speaker had made experiments which had led him to the opposite conclusion. Tuberculosis had hitherto been observed in all domestic animals, most frequently in poultry and cattle. The tuberculosis of poultry differed so much from human tuberculosis that it might be left out of account as a source of infection. Bovine tuberculosis remained to be considered. During the last two years, in conjunction with Professor Schütz, of the Veterinary College in Berlin, he had carried out a series of experiments. A number of young cattle which had stood the tuberculin test, and might therefore be regarded as free from tuberculosis, were infected in various ways with pure cultures of tubercle bacilli taken from cases of human tuberculosis; some with the tuberculous sputum of consumptive patients direct. In some cases the tubercle bacilli or the sputum were injected under the skin, in others into the peritoneal cavity, in others into the jugular vein. Six animals were fed with tuberculous sputum almost daily for seven or eight months; four repeatedly inhaled great quantities of bacilli, which were distributed in water, and scattered with it in the form of spray. None showed any symptoms of disease, and they gained considerably in weight. From six to eight months after the beginning of the experiments they were killed. In their internal organs not a trace of tuberculosis was found. At the point of injection small suppurative foci had formed, in which a few tubercle bacilli could be found. This is exactly what occurs when dead tubercle bacilli are injected under the skin of animals

liable to contagion. They were affected by the living bacilli of human tuberculosis exactly as they would have been by dead ones; they were absolutely insusceptible to them. The result was different, however, when the same experiment was made on cattle free from tuberculosis with tubercle bacilli from the lungs of an animal suffering from bovine tuberculosis. After an incubation period of about a week, severe tuberculous lesions were found in the viscera of all the animals.

An almost equally striking distinction between human and bovine tuberculosis was shown by a feeding experiment with swine. Six young swine were fed daily for three months with the tuberculous sputum of consumptive patients. Six other swine received the bacilli of tuberculosis with their food daily for the same period. The animals fed with sputum remained healthy; those fed with the bovine bacilli soon became sickly, and half of them died. After three months and a half, the survivors were killed and examined. In those fed with sputum no trace of tuberculosis was found, except here and there little nodules in the lymphatic glands of the neck, and in one case a few grey granules in the lungs. The animals, on the other hand, fed on the bovine bacilli all showed severe lesions, especially tuberculous infiltration of the greatly enlarged cervical lymphatic glands, the mesenteric glands, and extensive tuberculosis of the lungs and spleen. The difference between human and bovine tuberculosis was not less striking in similar experiments on asses, sheep, and goats. Thus, human tuberculosis differed from bovine, and could not be transmitted to cattle.

But what of the far more important question of the susceptibility of man to bovine tuberculosis? A direct answer was not possible, because experimental investigation was out of the question. However, there were certain facts bearing on it. Milk and butter often contained large quantities of the living bacilli of bovine tuberculosis, which numbers of persons daily consumed without becoming infected. It was thought that tuberculosis could be conveyed by alimenta, but primary tuberculosis of the intestine is extremely rare. In a large number of necropsies in cases of tuberculosis, Koch had seen primary intestinal tuberculosis only twice. At the Charité Hospital, in Berlin, ten cases of primary tuberculosis of the intestine occurred in five years. In 933 cases of tuberculosis in children, Baginsky never found tuberculosis of the intestine without simultaneous disease of the lungs and bronchial glands. In 3,104 necropsies in tuberculous children, Biedert observed only sixteen cases of primary tuberculosis of the intestine. Such cases were as probably due to the widely propagated bacilli of human tuberculosis as to those of bovine tuberculosis. Hitherto it could not be decided with certainty whether tuberculosis of the intestine was of human or of animal origin. Now they could be diagnosed. All that was necessary was to cultivate the bacilli and inoculate with them cattle by subcutaneous injection. Koch estimated that the extent of infection by milk and flesh of tuberculous cattle was hardly greater than that from hereditary transmission, and therefore he did not think that precautions against it are advisable.

As the main source of infection was the sputum, it was against that that measures should be directed. In the crowded homes of the poor perfect precautions were impossible. Whenever the consumptive coughed, he scattered the bacilli about. Thus whole families were infected. The infection might even spread to the neighbors. The admirable investigations of Biggs had shown that in the densely populated parts of New York regular foci of the disease were formed. Suitable hospitals should be established to which poor consumptives should be removed, so as to avoid their being a source of infection to others. This was a field for the activity of municipalities and of private benevolence. As this measure could not be carried out completely for a long time, other measures should also be resorted to. Obligatory notification—but only of cases where domestic conditions formed a source of danger—was especially valuable. Such limited notification had been introduced in Norway by a special law, in Saxony, and in several American towns. Disinfection of beds, clothes, and dwellings, when a consumptive died or changed his residence, was also important. The use of sanatoria had lately come into the foreground. About 5,500 beds had been established in sanatoria in Germany, which, with an average of three months' residence, would accommodate 20,000 patients annually. About 20 per cent. of the patients treated in them lost the bacilli in their sputum. But there were 226,000 persons in Germany so far gone in consumption as to require hospital treatment. Sanitoria were thought by some to be the only means of warfare against tuberculosis, but they were really of subordinate value. General prophylaxis, as shown by Cornet's figures, had led to a reduction of the mortality from tuberculosis in Prussia from 31.4 per 10,000 before 1889 to 21.8 in the years 1889 to 1897. In New York the exemplary sanitary measures of Biggs had reduced the mortality by more than 35 per cent. since 1886.

Lord LISTER said Dr. Koch's address was full of profound interest. That which riveted his attention was the startling view as to bovine tuberculosis being incommunicable to man. If that should be proved correct their work was simplified. Even if the human disease could not infect cattle, the converse did not follow, and it would be of the most serious consequence should they relax their efforts to secure a safe milk supply and then the view put forward prove erroneous. The variety of intestinal infection was the main argument, but mesenteric tuberculosis existed and was not rare in children. The matter was so important that he would call on specialists to speak on it.

Professor NOCARD, of Alfort, France, though admitting the value and interest of the address, repudiated the conclusion as to the non-communicability of bovine disease. He held that experimental researches in France proved tuberculosis to be transmissible from man to cattle and vice versa.

Professor BANG, of Copenhagen, could not accept Dr. Koch's conclusion, and feared the opinion of so great an authority might prove detrimental by causing a relaxation in the efforts now being made in all directions to secure the purity of milk.

Professor SIMS WOODHEAD joined in the tributes of previous speakers to Dr. Koch's great services, but he could not suppress his own conviction that bovine tuberculosis had played a onsiderable part in the extension of the disease among mankind. He suggested that the view put forward by Professor Koch should be tested by experiments under the Department of Agriculture.

In the evening the Lord Mayor and Lady Mayoress gave a reception at the Mansion House, the attendance at which was very large, many of the members being accompanied by ladies.

Third Day—Wednesday, July 24, 1901.

The Measures Adopted by Different Nations for the Prevention of Consumption.—Professor BROUARDEL, Dean of the Faculty of Medicine of Paris, delivered an address with this title. The Rt. Hon. Henry Chaplin, M. P., President of the Local Government Board, who presided, introduced him as the most distinguished authority on sanitary science in Europe. Professor Brouardel, speaking in French, said that the mortality from tuberculosis varied in different countries. In some it was accountable for a sixth, in others a fifth, and in others a fourth of the total mortality. Long before the infectiousness of tuberculosis was discovered, the struggle against it was commenced in England. The English, convinced by observation that tuberculosis thrived in damp dwellings, in 1836

passed a law providing for the construction of healthy houses. Since then more than ten acts of Parliament to render salubrious the dwellings of the poor had been passed and the mortality from tuberculosis had been reduced forty per cent. The anti-tuberculous education of public opinion which was now progressing was of great importance. In 1899, under the presidency of the Prince of Wales, the National Association for the Prevention of Tuberculosis was formed. Its object was to further prevention by educating the masses. Germany had founded societies for the erection of sanatoria and the popularization of sanitary ideas. In France the Society for the Prevention of Tuberculosis by Popular Education had collected those who could teach with authority, such men as Lavisse, Matignon, Victorien Sardou, Landouzy, etc. They addressed meetings and explained the methods of prophylaxis. Professor Brouardel, as President of the Polytechnic Association, had performed the same service in Paris. This year thirty-eight lectures had been given to 12,000 pupils. Thus, gradually, in all countries, the public were beginning to realize that personal care and cleanliness were necessary, that a consumptive was only dangerous when necessary precautions were neglected, and that the danger lay in the sputum. Professor Brouardel related, amidst great applause, the case of an American millionaire who was fined $5 for the offence of expectoration, and on the second occasion was sentenced to twenty-four hours imprisonment. England had the great merit of recognizing the evils of insalubrious dwellings, and passing laws ordering their destruction; and, further, of enacting laws for the erection of sanitary dwellings which had been supplemented by the beneficence of private individuals. Since 1836 the mortality from consumption had been reduced about forty per cent. by improved dwellings. Healthy houses are anti-tuberculous. Unhealthy, overcrowded dwellings are foci of contagion.

The "wretched lodging," said Jule Simon "is the purveyor of the public house." In 1850 a law was passed in France dealing with unhealthy dwellings, and another in 1894. In the crowded parts of towns tuberculous foci were created which were a source of danger to the inhabitants. In Paris the mortality from tuberculosis varied in different districts from 10 to 100 per 10,000 inhabitants. Alcoholism he regarded as a most potent factor in propagating tuberculosis, for it rendered the strongest man powerless to resist the disease. Hence the high mortality from tuberculosis in classes addicted to drink. Tatham's figures showed that, taking the mean mortality from tuberculosis at 100, that of barmen was 257; of brewers 148; of publicans 140. Ministers of State like to calculate the amount they obtain from duties on alcohol; they should deduct the cost to the community of the ruined drunkard and his degenerate, scrofulous, and epileptic children. The danger of infection is everywhere and inseparable from our civilization. It lurks in our food. Chauveau had shown that intestinal tuberculosis was produced by infected food. Without desiring to exaggerate, the speaker could not overlook the danger in milk and meat. To prevent it, he urged strict inspection, and, until the necessary legislation was adopted, the boiling of milk. The theory that boiling milk makes it less nutritious he repudiated. The idea that tuberculosis could be cured dated back to Hippocrates, who said: "Phthisis, if treated early enough, gets well." In 1838, Carswell, one of England's most distinguished physicians, wrote: "Pathological anatomy has never, perhaps, given a more decided proof of the cure of a disease than of phthisis." Laennec, Guillot, Letulle, and others found that in more than half the necropsies performed there were old healed tuberculous lesions present. Professor Brouardel had found at the Morgue in Paris, where he frequently made necropsies in cases of accidental death, that in half the cases, if the person had lived in Paris for ten years, healed tuberculosis lesions, cretaceous or fibrous, were present. In order that treatment might be of service in the early stage, M. Calmette conceived the idea that, instead of waiting for the workmen to come, the doctor should seek him. He opened an anti-tuberculous dispensary at Lille, which had been eminently successful. Another had been established in Paris. The best way to ferret out the disease was to have an agent-workman who would notice when his comrades began to cough, and advise them to go to the dispensary; who, alive to the dangers of a badly kept workshop, would superintend its cleansing. Professor Brouardel touched on the question of sanatoria. He said that in Germany there were 53 open, or ready to be opened. Of those who left the sanatoria in a satisfactory condition it had been shown that, in 1896, forty-six per cent. were able to work; in 1897, forty-seven per cent.; in 1898, fifty-eight per cent., and in 1899, sixty per cent. In France several sanatoria had been opened, and others were in process of erection. Professor Brouardel concluded with an eloquent peroration, saying that, by a united effort, the whole of the civilized world might succeed in exterminating the cruelest scourge that had ever fallen on it.

Mr. CHAPLIN referred to the address of Professor Koch on the previous day, and to the two Royal Commissions which had examined the question of tuberculosis in cattle. One of those bodies it had been his duty to nominate. Both reported that the disease could be transmitted from man to animals and conversely. Of that universally held opinion it seemed that one-half was disproved and the other required to be re-examined. He did not presume to express an opinion on the subject, but he looked with confidence to the judgment of such distinguished men as he addressed. He moved a vote of thanks to Professor Brouardel for his important address, which was seconded by Professor Gerhardt and carried unanimously.

In the evening the Royal Institute of Public Health gave a dinner in honor of Dr. Koch, to whom had been awarded the Harben medal. The President, Professor W. R. Smith, after the loyal toasts, presented the medal and the diploma of Honorary Fellowship. He then said that he had received a letter from Mr. Chamberlain accepting the Honorary Fellowship, and regretting that he was prevented being present to pay his respects to their honored guest. Mr. Balfour also wrote to express regret that he was prevented from being present. The President explained that the medal was placed at the disposal of the Institute by one of its oldest friends to be given for eminent services to public health, rendered by persons of any nationality. Up to the present only four persons had received the medal, viz., Sir. J. Simon, Lord Playfair, Lord Lister, and Professor Pettenkoffer. Dr. Koch returned thanks for the honor conferred upon him and the appreciation of his work by his English colleagues. The diploma of Honorary Fellowship was then presented by the Chairman to Lord Strathcona.

Fourth Day—Thursday, July 25.

There was a very large gathering at this meeting, when Earl Spencer took the chair and introduced Professor McFadyan, who was to read the address in which it was anticipated he would present views in absolute contradiction to those enunciated by Professor Koch. His Lordship cordially supported Mr. Chaplin in what he had said the previous day, and strongly advocated a government inquiry.

Tubercle Bacilli in Cow's Milk as a Source of Tuberculosis in Man.—Professor MACFADYEN strongly controverted the position taken by Koch in his paper read two days previously. He said that the identity of human and bovine tuberculosis was generally supposed to have been finally determined by Koch himself, when he discovered that the bacilli were identical in morphological, tinctorial, and cultural characters. Hundreds of other workers had brought to light additional evidence of this identity, such as the specific reaction in tuberculous cattle from tuberculin, whether human or bovine. He did not deny that the bovine bacilli were usually more

virulent to cattle and other domesticated animals than human bacilli. But this did not prove that bovine bacilli were only feebly pathogenic to man. Moreover, since these bacilli were highly dangerous to such diverse species as the rabbit, horse, dog, pig, and sheep, it was probable that they were also dangerous to man. As to Dr. Koch's argument that cases of primary intestinal tuberculosis from milk or meat were extremely rare, the observations of others differed. In the Hospital for Sick Children in Great Ormond street, London, Dr. Still found that in 29 per cent. of the cases of tuberculosis primary infection appeared to have taken place through the intestine. In the Children's Hospital at Edinburgh, Dr. Shennan found 28 per cent. The late Sir Richard Thorne was convinced that tuberculous milk was the main cause of tabes mesenterica in children. His reason was that the statistics for the last fifty years show a marked decline in the death rate from phthisis—the form of tuberculosis resulting from inhalation, while only a slight decline took place at all ages in the death rate from that form of tuberculosis which is ascribable to alimentary infection; and in children under one year there was a notable increase. The number of persons who became infected by milk could not be ascertained, but some estimate might be formed from certain facts. About 30 per cent. of all the milch cows were tuberculous in some degree. But the milk did not appear to be dangerous until the udder became diseased, and only about 2 per cent. of milch cows were so affected. Milk from a tuberculous udder contained bacilli in enormous numbers; but the disease was not attended by any pain or tenderness for a considerable time, so that the gravity of the condition was not realized. To prevent this danger Professor McFadyen advocated a periodical examination of cows by competent inspectors. Less effective but more easily carried out measures were a compulsory notification of udder disease, and of any symptoms of tuberculosis in milch cows, and the interdiction of sale of milk from animals suffering from this disease. He also referred to the advantage of heating milk so as to sterilize it. To justify the legislation he advocated it was by no means necessary to contend that the danger from milk equaled that from sputum. The latter was undoubtedly the great cause of the spread of human tuberculosis, and every practicable means of preventing infection in that way should be employed; but he could not concede to milkmen the right to sell tubercle bacilli, even if we were assured that—like Dr. Koch's experimental pigs—we had only to fear the development of "little nodules here and there in the lymphatic glands" of our necks, or "a few gray tubercles in our lungs." Much laughter mingled with loud cheers marked the conclusion of the address.

In the discussion which followed Drs. Nocard of France, Crookshank and Sims Woodhead and Ravenel of the University of Pennsylvania, expressed their views as being in complete accord with those of Professor McFadyen that bovine tuberculosis was a real danger to man.

Sir J. Crichton Browne moved a vote of thanks to Professor McFadyen for an address which showed how fascinating he had made a rather grim subject. He mentioned that Dr. Brown, the representative of Wisconsin, had telegraphed to his government with the result that the State bacteriologists had already begun experiments. He hoped there would be no delay in this country and that meantime we should run no risks.

Dr. Hamilton, of Aberdeen, seconded the motion, which was also supported by other speakers and carried.

SECTION II—MEDICAL, INCLUDING CLIMATOLOGY AND SANATORIA.

First Day—Tuesday, July 23d.

The president, Sir Douglas Powell, welcomed the visitors, both British and foreign, and gave a brief outline of the intended programme of the Section.

Discussion in Climatology.—With regard to the day's proceedings, he said the morning would be devoted to a discussion on the influence of climate on consumption. He pointed out the general tendency of tuberculous lesions to heal if placed under suitable conditions, and kept free from causes of contamination, septic or otherwise. Climates, varying as they do in temperature, moisture, freedom from dust, etc., must exercise a varying effect on the patients. It was well known that, broadly speaking, Switzerland, Egypt, and the Riviera were good climates for tuberculous cases; what was wanted was to examine different localities in detail and endeavor to ascertain whether similar conditions on a more restricted scale could not be found in these islands; also whether treatment as carried out in sanatoria was at the same time needful; personally, he was inclined to disapprove of the excessive gain in weight under superalimentation.

Dr. C. Theodore Williams then read a paper on "What Influence Has Climate on the Treatment of Consumption and How Far Can Cases be Grouped for Treatment in certain Climates?" He pointed out that the belief in the favorable influence of change, *i.e.* change of climate from the mountain to the seaside, or from the plain to mountainous regions, was no new idea, but had existed in all ages. In Great Britain, sea voyages had been specially believed in, and there was much to be said in their favor. A few years ago, voyages were very commonly recommended, and all could remember striking cases of improvement. They were not so frequently advised now for reasons to be given later on. The fact was that well attested cases of arrest of tuberculosis in a variety of climates and under widely different conditions could be found in the records. To get the full value of any climatic treatment, the patient must be kept more or less completely under the influence of the atmosphere, that is, in the open air; and all climates, such as the tropics and very moist climates, for example, were not suitable for open-air life. Of all climatic factors sunshine was the most important. The climates suitable for tuberculous patients could be classified as (1) marine, (2) dry, warm, and (3) mountain climates.

In marine, he included the English south and southwestern coast health resorts. The number of rainy and also cloudy days was a drawback; the wind he did not disapprove of, but thought a moderately windy locality, where there was suitable protection by wind shelters, favorable. Wind was a great ventilator, and ventilation was especially important for the phthisical. In favor of these places was that they were easily accessible, the food supply was good, and there was abundance of medical skill. They were suitable for early and for advanced cases. Then, again, many patients could settle down permanently and make their homes in these towns. As far as the British climate was concerned, it was certainly suitable for most cases. In warm marine climates he included Madeira, the Canary Islands, and some of the West India Islands. Many catarrhal cases and cases of laryngeal tubercle were benefited at such places. Lastly, he would mention sea voyages of, say, three months' duration, with a month interval before undertaking the return journey. The trip to Australia and New Zealand via the Cape fulfilled all indications. Tropical regions should be avoided as much as possible; in case of the Australian journey, the Red Sea route was highly dangerous. Loss of weight was apt to occur in the tropical regions. One drawback was the lack of exercise on steamers. The Brazilian and West India trips were also very good. A deck cabin was best, and sleeping on deck was advisable whenever possible. It was essential on a voyage to have good food and proper cabin accommodation.

Of dry, warm climates—desert climates—Egypt and the Libyan desert, were most characteristic. The atmosphere was very pure and aseptic, and life in a tent was not unpleasant. Of these climates, he would place Egypt first in point of improvement, but he had never seen such

absolute cures as in high altitudes. Still, chronic cases with cavities, and advanced cases, often did very well. In this division he included the Mediterranean basin—Riviera, Algiers, Tangier, and Spain. The climate at these places was dryer than in England, but less dry than the desert, the atmosphere was clear and free from fog or mist. Patients likely to be benefited by dryness, sunshine, cool winds, and moderate warmth, could not do better. The nights were cool, and patients could be in the open all the winter. The chief drawback was that patients did not take the needful medical precautions, and that sanatorium treatment was not very systematically carried out. His statistics of these places had not been good so far, but in individual cases he had known good results, especially in prolongation of life in cases where cure was not to be expected. The most suitable cases were those of the spumous type—laryngeal phthisis, unilateral pulmonary cases, and cases preceded by inflammatory attacks.

Next, mountain climates were considered. These, like other climates, vary with latitude and altitude; but mountain atmospheres possess certain peculiarities due to rarefaction, alteration of diathermancy, variation of atmospheric pressure, and asepticity. At first the pulse and respiration are quickened at high altitudes, but after acclimatization again fall, the thorax dilating, and its walls becoming more mobile, especially when much exercise is taken. Large thoraces he considered typical of mountain dwellers. Of cases sent to high altitudes he had statistics of 385 observed during 1878 to 1900—275 males and 110 females; average age in males 29, females 26; average duration of disease before climatic treatment adopted, 2 years and 5 months; 143 cases had a tuberculous family history, and there had been a history of hæmoptysis in 43 per cent.; 36 per cent. were bilaterally affected, 74 per cent. unilaterally, 34 per cent. had cavities. They were, therefore, by no means selected cases. The average duration of stay in the mountains was 11½ months. Most of these patients were at Davos, some in Colorado, and a few on South African highlands.

The general results, he concluded, were that 87 per cent. improved—45 per cent. of the total completely recovered; 1 per cent. remained stationary, and 12 per cent. had died, *i.e.* seven-eighths improved, one-eighth deteriorated. Gain in weight had not been particularly common. The incipient cases did better than excavation ones, but still many of these latter improved. How many had relapsed he could not say, but not many of the 320 he had information about.

In conclusion, he was of opinion that residence in mountains helped to cure by causing hypertrophy of the surrounding healthy lung—that possibly the arrest of the disease was partly directly due to effects of pressure thus induced, and anæmia of the affected areas; these local changes were accompanied by disappearance of general symptoms. But for acute catarrhal cases, those with double cavities, and laryngeal cases mountain treatment was contraindicated.

In order of value in his opinion he would place: 1. Mountains. 2. Sea voyages. 3. Riviera and desert. 4. Home climates.

Dr. Burney Yeo regarded the modern climatic or open-air treatment as being new only in attempting hyper-aeration of the lungs by living in the open air, and in doing so there must always be a risk of setting up catarrhal conditions. Sydenham, between two and three centuries ago, had the open air cure in his mind when he said that riding sufficiently long journeys on horseback was the best cure for consumption. Climatic and open-air treatment was essentially the same thing, and the speaker considered it difficult to establish any suitable classification of cases fitted for certain climates. One of the most striking cases of arrest of phthisis he had ever seen was in a lady who left the country and came to live in London. She married, bore children, and died of heart disease, her phthisis having become cured. Another remarkable case he related, which had never been farther than Hastings. Many patients with chronic disease travel about to different winter resorts and seem to improve in all of them. The term "incipient" phthisis should be dropped and "early" adopted. Incipient seemed to suppose a pre-phthisical condition. The term "tuberculous" phthisis was still more objectionable—his mind failed to grasp a "non-tuberculous" phthisis.

The value of sea voyages he considered grossly overestimated and the drawbacks, which were serious, not realized. Consequences often dire ensued, and much discrimination was needful in selecting cases. A writer, a scientist well known in another branch of science, had written in this connection: "The uncertainty of the influences to which he or she may be exposed . . . embarked upon a voyage, crowded in a close cabin, lying on a narrow hard shelf, . . . perpetual din of the engines, etc." Another writer had pointed out that any advantage due to the pure air was done away with by the close, ill-ventilated cabins, dampness, draughts in the saloons, enforced confinement in bad weather, besides the horrors of seasickness. To a large extent then he differed from Dr. Williams as to the value of sea voyages. Patients with advanced dyspnœa should not be sent away from home. But if they insist on going Madeira or Malaga should be selected, because the warm equable climate is most suitable for the bronchial catarrh present in such patients. Warm, equable climates do not cure, but they often materially prolong life.

Mere equability of temperature was to be avoided in early cases—wide diurnal variations, if regular, were more suitable, and had a much more invigorating effect. In our own climate the variations of temperature were so irregular that it must always be unsuitable for catarrhal cases. In advanced cases with febrile disturbance bed is the best place. High mountain air had the widest range of application in moderately advanced cases, but febrile or cachectic cases or patients with gastric disturbance did better at marine resorts. Tuberculous patients with emphysema he considered unsuitable for mountains, also those with renal complications, on account of sensitiveness to cold. Persons peculiarly sensitive to cold from any cause must not be sent to high altitudes. In our own country we must look for suitable local climates and conditions for sanatoria. Thus it had been said that at Nordrach patients got well in spite of climatic conditions—Germany was certainly not a good climate for tuberculous cases—but then at Nordrach all the local conditions—altitude, rainfall, woods to form wind screens, etc., were suitable. The speaker considered that care without climate was better than climate without care. Suitable climate relieves catarrhal cases, raises nervous and muscular tone, relieves the muscular debility, favorably influences digestion, and benefits the moral and mental state. Patients seen very early may be permitted a certain latitude of choice of locality, but for prolonged febrile cases repose in bed at home is the best. In other advanced cases, home or a warm marine climate, for catarrhal cases a warm marine, in the scrofulous type a bracing marine should be selected.

Professor Lannelongue, of Paris, read a paper on the influence of different climates and of individual resistance in experimental tuberculosis. It was found that, as far as climatic influences could be studied in experimentally induced tubercle in animals, very little effect could be noted one way or the other, and that the chief factor was the individual resistance.

Dr. Hermann Weber of the German Hospital, London, referred to his experiences among the class of patients attending the hospital. They were often working and living under very adverse circumstances—*e.g.* baking or clockmaking. He had often said to such patients, "You must give up the bakehouse, and go round with the bread cart instead," or "You must stop clock-

making, and get your living by taking clocks around to sell." In many of them the effect had been marvelous. He had been accustomed to do this before he had learnt about the "open-air cure"; now one would hesitate to give such advice, as rest had been made such an important factor.

His experience of marine climates had not been good. Tuberculous patients bear high winds badly, and the winds at marine resorts were often high. He referred to the work of recent observers with regard to the distribution locally of phthisis in the Isle of Man and in parts of Devonshire, taken into conjunction with the direction of and exposure to the prevalent winds. Such observations had tended to show that there was an intimate connection between wind exposure and consumption. Of the Riviera his experience had been bad, but perhaps that had been due to absence of proper sanatoria and systematic treatment. About sea voyages he had gladly noted Dr. Yeo's remarks—the frightful sufferings of bad sailors, and in any case eight hours a day in a cabin must not be lightly regarded. From warm, dry climates, such as Egypt, he had seen bad results, but perhaps with a sanatorium at Helonan, better might be expected. All observations should be divided into before and after sanatorium treatment. Many cases were lost by imprudent actions, often only an hour or so of improper exposure, due to want of supervision. He did not believe the snow melting period on mountains to be injurious, as was generally thought.

He had a high opinion of climate, but a still higher of properly directed hygienic and dietetic treatment, and it was possible, he said, to cure the majority of cases in England if taken early either in sanatoria or in their own homes.

Dr. Charles Denison, of Denver, pointed out the essential and intimate connection between residence at high altitudes and out-door life in appropriate localities. The more rarified the air, the larger the volume to be allotted to each person in order to afford the requisite supply of oxygen. The bad effects of deficient ventilation were increased and rendered more obvious by altitude. As more and more air space became necessary, outdoor life became a necessity. No absolute immunity from infection was guaranteed by any altitude whatever. In Colorado tuberculous infection, however, was very rare; it was almost all imported. The mortality from tubercle in Denver, and in Colorado generally, was very low—only two per cent. Many of these cases were meningeal, and in many the conditions of ventilation under which they developed were very bad. That tubercle was not acquired in the open air he considered proved by the freedom of the Western cattle from tuberculosis, compared with the frequency of the same in cattle and animals generally under domestication.

Sir J. W. Moore, of Dublin, was of opinion that climate played a very secondary part in phthisis. He referred to the case of a coachman, living with his family in one small, ill-ventilated room. The man died of phthisis, and no precautions to prevent infection having been taken, his wife and one son developed the disease. But they had subsequently recovered with no climatic change. He thought that experience showed that the climate of the British Isles was suitable to recovery if proper precautions were taken. He related a case of the great Stokes. The patient was a gentleman who was told he had only six months to live. The patient decided to live as he pleased for that period, and spent his time duck shooting. At the end of the period named, he walked into Stokes' consulting room cured. The speaker deplored the profound ignorance of the public generally as to the value of sunlight and fresh air. In coming into London he had noticed how all the people kept their windows shut. As an example of the harmlessness, or, rather, invigorating qualities of even night air and in winter, he related an anecdote of the present Sir William MacCormac's father, who came one night into Sir William's bedroom, when he was a lad, and found him asleep with the window wide open, and drifted snow lying on the coverlet.

As to sea voyages, since many people were unable to stand the profound depression of localities where hygrometric observation showed the air to be nearly saturated, how could they possibly stand the atmospheric conditions on a voyage? In addition, the air on steamers was often overheated and cabins were ill ventilated.

Dr. W. R. Huggard, of Davos Platz, could not agree that climate was without importance; but a suitable climate must be selected. Many unsuitable cases, in his experience, came or were sent out to Davos. No one climate was best for all cases, and for every climate there were unsuitable cases. But he did not consider the duration of the disease, or presence or absence of cavities, relevant. The principles to guide one were the physiological actions of different climates. Of these, the heat-abstracting power was the chief. This heat-abstracting power might be small or large. Thus it might be small in a cold climate in the absence of wind. Dry climates were never regular in temperature, but regular in heat demands. High altitudes have high heat demands and the response depends on the patients' heat-producing power and power of response. Young people usually respond readily to a higher demand for heat production. The cold day air of Alpine health resorts he considered unsuitable to persons of weak circulation or digestion or small lung capacity. Wind and dust were drawbacks to American and South African mountain resorts. The Riviera was suitable for catarrhal cases, and old and not vigorous people. Hæmoptysis should be divided into two categories—the hemorrhage of early cases and that of old cases with large cavities. The early hemorrhagic cases do well in the mountains. He thought insufficient importance was made of the thorough disinfection of rooms after habitation by phthisical persons.

Dr. F. M. Sandwith, of Cairo, Egypt, said that previous speakers had pointed out the differences between mountain and desert air. What struck him and many others was the similar effect of the Egyptian desert air and that of European mountain regions. What it was due to—ozone or other ingredient—he could not say. But it was a fact that people on going into the desert often exclaimed that the feeling of the air was like that on the mountains. During eighteen years' residence in Cairo he had seen only one case of tuberculosis develop in a European in the country. He was an officer and had been home on leave, so might have contracted it in England. On the other hand, it was common among the natives. The climate, then, was not the cause of the difference. The inference was in favor of the sanatorium view, the natives and the Europeans living under such diverse conditions. The ventilation and general sanitary conditions of the native dwellings were bad in extreme. In Egypt a large class of men, professional and otherwise, existed, who originally went there for lung trouble and had improved well enough to settle down and get their living.

Dr. Amrein, of Arosa, gave a bacteriological summary of the conditions met with in that locality, and referred to the physiological changes induced thereby. Chief among these was the increase in the number of red corpuscles—hæmoglobin, microcytes, and nucleated red corpuscles appeared. These blood changes were physiological and due to the low air pressure—not temperature. Clinically, he himself was an example of arrested phthisis—great improvement was seen, weight increased, night sweats and febrile disturbances disappeared, as did nervous troubles. One great advantage of mountain treatment was that any time of the year was suitable for it; another that patients were hardened against their return to ordinary life, not enervated as in milder climates.

Then the Secretary read a paper of the late Dr. Carl Ruedi, of Arosa, in which chest measurements, tracings, and methods were described. The observer had found, contrary to the commonly accepted opinions, that the affected side was at first more largely developed than the

sound one, and that only later on when cicatrization ensued did the diseased side become contracted. His tracings also showed that high altitudes were the best regenerators of lost lung tissue after the disease had become arrested.

Dr. HOBHOUSE, of Brighton, agreed with Dr. Huggard that one must regard the constitution of the patient rather than the class of the disease. Cold especially must be considered, many patients being much depressed thereby. The risks of a sea voyage were enormous. To be shut up between decks for three or four days was destructive to all conditions of health. He had seen even old fibroid cases with labored hearts do well in Colorado, but he would be chary of selecting any particular climate as suitable for all of any one class of cases.

Dr. CROSBY WALSH, of Tasmania, pointed out that the Tasmanian climate represented the best points of the English climate. Consumption did well there, but as yet no sanatoria existed. The natives enjoyed a wonderful immunity from phthisis. In sending patients out sailing vessels should be selected, not steamers.

Dr. Williams, in reply, referring to Dr. Weber's remarks about wind, pointed out that it was not the wind *per se*, but the damp accompanying it, that did the mischief. This was peculiarly the case in Devonshire with its wet southwest winds. Personally he liked and believed in wind, but advised that a shelter be used. In sea voyages, of course, food, cabins, etc., must be good, and patients must live on deck, defying the weather. Patients must not be sent to sea to be coddled. He did not maintain that England would not suit many cases, but wanted to ascertain what climates should be selected for those that home did not suit; and whether if they did do well here, they would not do still better at high altitudes. How climate could possibly be set aside as of no importance he could not understand.

Second Day—Wednesday, July 24.

On this day the Pathological Section united with the Medical in a joint discussion on:

The Value (Therapeutic and Diagnostic) of Tuberculinin Human Tuberculosis.—Dr. HERON opened the discussion in a paper in which he traced the history of the use of tuberculin, and his own experience with the treatment. In his opinion it had fallen into discredit on account of (*a*) its frequent use in unsuitable cases, (*b*) too large doses being employed, (*c*) giving it before the temperature has been normal for twenty-four hours, (*d*) neglecting to diminish the dose on a rise of temperature, (*e*) prejudice on account of the severe symptoms that sometimes follow the injection. Since March, 1897, Dr. Heron had used only the new tuberculin, with which he had treated ten cases in hospital. One was a case of lupus. In December, 1900, three were well and supporting themselves by their work; three were lost sight of; one was well until lately, when recurrence took place; two died, being hopeless when admitted. One of these patients was shown at the clinical society in February, 1898, when there was a discussion upon its nature. Dr. Heron thought tuberculin as safe as any potent drug, and he had used it altogether in above 2,000 cases.

Professor KOCH stated that when in 1890 he first introduced tuberculin to the profession, he was able to point to two important properties which were, first, its power of producing a reaction in tuberculous patients, and thereby affording a means of great diagnostic value; and, secondly, its curative therapeutic effect if used for a considerable period. As to the first property, millions of injections in men and animals had demonstrated its use to be free from danger, and study of the results showed them to be of diagnostic value in 97 to 98 per cent. of the cases. In human beings small doses should be given, and if needful the experiment repeated. The method to be adopted was to observe carefully the patient's temperature for two days, and if it rose above 37° C. not to use tuberculin. With a weak patient, 0.1 mg. should be used; in cases of stronger patients, when suspected lesion was not extensive, a larger dose might be used; but in no case more than 1 mg. If no rise of temperature followed the administration, one should wait two days and administer an amount double that first given. If a slight reaction ensued, the dose should be repeated—that is, a dose of the same amount, not a double one. In many cases the repetition produced a reaction far greater than the first dose. If so, this was an infallible sign of tubercle. If no reaction followed, one might go on, if necessary, to 5 or even 10 mg. If this method were carefully followed, no danger or hardly even discomfort was caused—the ensuing rise of temperature being well within that which a patient could easily bear. Of his own personal knowledge of 2,890 injections, no ill results followed, and the rule was either distinct reaction or absolute non-recurrence. Very often the local symptoms, as well as the general reaction, afforded a further key as to the site of the disease. This method was especially valuable in catarrh of the apex. In 15 per cent. of such cases no reaction took place, and in all these the subsequent history of the case showed them to be non-tuberculous. Every case of pleurisy, of course after febrile symptoms had subsided, should be subjected to the test. In such, 72.2 per cent. had given a typical reaction. Pulmonary tuberculosis, in its very early stage, was curable, and therefore the tuberculin test was most important, as leading to early treatment. In selecting cases for sanatorium treatment tuberculin was of special value.

Its therapeutic value was great if the application was restricted to curable cases—cases not too far advanced, and cases not complicated by other morbid processes or the presence of streptococci, pneumococci, or influenza bacilli. In these mixed infection cases the temperature was usually raised, and tuberculin should not be used. But in uncomplicated, non-febrile cases tuberculin was curative.

One must not attempt to obtain severe reactions; the reaction must be kept as slight as possible, and the administration must not be repeated until the temperature has fallen and all reaction has passed off. Dr. Goetsch uses such small doses that no reaction ensues, and with very good results.

Further, the tuberculin treatment should be resumed after three or four months' interval of apparent cure. Experience had formulated certain rules for its administration. They were (1) patients free from fever, and in whom the morbid process is not too advanced, should be selected; (2) begin with a small dose, and increase it so slowly that no reaction, or a very slight one ensues; (3) do not repeat until the temperature has again been normal for one to four days; (4) repeat the treatment after an interval of from three to four months.

Sir DOUGLAS POWELL remarked that both speakers had stated tuberculin must not be used if the temperature were raised. But in practice one did not get cases free from fever—they were already febrile. How must one act under these circumstances? And further, in active tubercle, if the temperature does fall to normal the physician is usually satisfied that the case is going on well, and is willing to let it remain so. Are we then to go on to the use of tuberculin?

In the cases of mixed infection which are so very general was he to understand that tuberculin was unsuitable?

Professor WILLIAM OSLER, of Baltimore, had for six years in the Johns Hopkins Hospital used tuberculin in doubtful cases, and considered its diagnostic value inestimable. The reports of his surgical colleagues as to its value were also favorable. In doubtful cases of early phthisis at one apex it was of great use. In answer to the query as to whether it was dangerous, in his experience it had proved uniformly harmless, with no single instance of any ill result.

Of its use as a method of treatment he had had of late years no experience, and he was impressed by its extreme limitation in use if only afebrile cases were to be selected. Such cases were rare. And if the temperature were normal,

if fresh air and a good diet were placed in the scale against tuberculin, he would certainly choose the former.

Dr. Fraenkel had had more improvement with tuberculin than with other remedies, and had learned to avoid the dangers of its use by experience. Febrile disturbance was a certain indication. Very small doses and very slow increase must be the rule, in order to avoid severe reactions. The practice of increasing dosage a hundred per cent. at a time was distinctly bad.

Professor Denys, of Louvain, described experimental peritoneal lesions produced by tubercle, and had found that if tuberculin were administered the lesions developed more slowly, and were in some cases cured.

Dr. Denison, of Denver, was of opinion that the majority of cases were curable by climate, exercise, and fresh air, feeding, and medical, surgical, and individual treatment. He considered that perhaps 20 per cent. were left in which tuberculin could be advantageously used. Of its diagnostic effect in 1,200 cases he had a very high opinion.

Dr. Theodore Williams was of opinion that there was no doubt whatever about the diagnostic value of tuberculin. The remarkable results of an injection of tuberculin had, as it were, captured the imagination and led to very high hopes concerning its use. The lesions were lit up so as to be seen. From a diagnostic point of view it certainly touched the spot.

As to its therapeutic value, Koch himself introduced great difficulties. The mixed infection type of case was very common. In the incipient uncomplicated cases, where tubercle bacilli were found with difficulty, where physical signs were slight, and the general health good, he had used tuberculin and carefully carried out Koch's method as described in print. In all of these what was observed was that lung tissue appeared in the sputum and a cavity quickly formed. This was the same in nine such cases he had observed, and the formation of cavities was a decidedly worse condition than infiltration.

Later on there was a decided change to contraction of the cavities and the patients described themselves as feeling better. But they came back later in a worse state than ever. In private practice his observations had been the same—in every case lung tissue appeared in the sputum, but the tubercle bacilli never disappeared. If used in pyrexial cases tuberculin tended to make a previously intermittent pyrexia continuous. He could not see what use it was in treatment. Under its administration the disease progressed, just the opposite to what we endeavored to obtain by all other methods of treatment. Instead of a building-up process a breaking-down one was brought about. His view was that its proper place was as a diagnostic agent, where it was unequalled. In this country we did not view these incipient, first stage cases as so serious. They were quite amenable to ordinary methods of cure. And as to the cures attributed to tuberculin he would say "call no man cured of tubercle until he is dead and his autopsy properly performed."

Professor McCall Anderson maintained that the use of tuberculin was safe, but its abuse fraught with danger. Small doses should be used to begin with and carefully repeated, as the reaction after a second dose was often greater than after the first. The stage of no reaction should be deferred as long as possible. As to its diagnostic value he could not understand how it was that, although its value had been so abundantly proved, and it was so constantly in use by veterinarians in connection with tuberculous cattle, we so seldom resorted to it in the case of human beings.

As to its therapeutic value, it was not now used in advanced cases, in which it was harmful rather than of use. In any case the usual open-air methods should be combined with the use of tuberculin. In external tubercle it was of the greatest value. His results had been very good in lupus vulgaris, lupus erythematodes and scleroderma. Relapses were apt to occur, but besides the tubercle bacillus, there was the soil suitable to its growth to be borne in mind. And we must therefore combat this predilection of the patient for tubercle by the aid of pure air, generous diet, and other recognized anti-strumous measures.

Dr. Vicary Snow, of Bournemouth, pointed out that in the cow there was not always a reaction after a single injection, and therefore the sale of tuberculous meat was not entirely prevented. As to the therapeutic value of tuberculin his observations were limited, but were quite opposed to those of Dr. Williams. His experience of three cases was that its use had been beneficial. In any case it was only an adjunct to treatment now, as present sanatorium methods rendered it less needful than formerly.

Dr. Bousfield, of London, maintained that one never saw cases until the temperature was raised. But his experience both with old and new tuberclin was that the temperature fell instead of rising. His opinion of it was favorable; one case in particular had been very successful. But he would like to ask Dr. Koch what we were to understand by tuberculin. Since Dr. Koch's speech of the day before, in which he stated that bovine tuberculosis was different from human tuberculosis, were we to have two tuberculins, one for animals and another for human beings? What was the source of the present tuberculin; was it derived from bovine tuberculosis? If so, our views would need modification.

Dr. Stone, of Boston, protested against its indiscriminate use as a diagnostic agent. He himself had been injected when it first came out years ago to test its harmlessness. The result was a typical reaction. But no signs of tubercle ever existed, or had subsequently developed. Of course he might have a tuberculous mesenteric gland—that his pathological friends might ascertain later on. Might not a reaction occur in a number of such cases? Enthusiasts admit a five per cent. error. He believed it was greater.

Dr. Eric France, of Claybury, pointed out that the death rate from tubercle in the insane was twelve times as great as among the general public. Asylums therefore afforded a very suitable field for the use of tuberculin. He had injected tuberculin in fifty-five cases of suspected tubercle, twenty cases in which tuberculosis was not suspected, and in himself. Of the fifty-five suspected of tubercle forty-five had reacted. Of these forty-five, thirty-four had since died, and on these thirty-four, twenty-nine post mortems had been made—in all of them active tubercle had been demonstrated. None of the non-suspects or himself gave any reaction.

Dr. Vivant, of Monte Carlo, agreed with Dr. Williams, that the therapeutic use of tuberculin in the cases where it did good was just where it was not needed, as such cases were curable by other means. What we needed was a remedy against tubercle in all its stages and forms. He would like to have an answer to the question concerning tuberculin, bovine and human—asked by a previous speaker.

Dr. Squire also asked whether the tuberculin used in cattle was the same as that used in mankind. He could not understand Dr. Heron not having seen signs of destruction of tissue after using tuberculin. In his experience both in Berlin and here such was the case. By increasing the activity of internal lesions it seemed to him that bacilli might be disseminated.

Dr. Möller, of Berlin, described the methods of using tuberculin that he had employed personally. Small doses beginning at one milligram and gradually increasing, and never going beyond ten milligrams should be the rule. He had never seen any ill results. But tuberculin alone did not cure, and must be combined with sanatorium treatment.

Dr. Otis, of Boston, would like to know what percentage of syphilis cases reacted in tuberculin. He had

found a few react. Of course there was always a doubt as to such being latent tubercle. Tuberculin should also be used as a test of cure. The cure was complete when the reaction no longer occurred.

Dr. HUGGARD, of Davos, had had two very successful cases. But in a later one where the disease was apparently arrested and temperature normal, on tuberlin being used a reaction occurred—tubercle bacilli reappeared in the sputum and never again disappeared. The arrested disease had been reawakened. In another case where there were tubercle bacilli in the sputum, no reaction occurred for some time, then a very explosive, violent reaction came about, followed by general tuberculosis. The impression left on his mind by these cases was so strong that he never again used tuberculin except at the express wish of the patient.

Professor NOLAN, of Leyden, would like to know what Prof. Koch means by a temperature of 37°C. Is the patient resting in bed, or up and about? Is the temperature to remain below 37° C. during the whole of the day? Every feverish reaction is not necessarily a sign of mixed infection. Mere work and movement may send it up.

Dr. Heron, in concluding the discussion, was surprised by the unanimity of opinion displayed. All the speakers agreed that the diagnostic value was an accepted fact. That being so, the value of tuberculin could not be overestimated, and at all events its therapeutic value indirectly was great, as it led to early detection and treatment. All agree that much smaller doses must be used than formerly. Goetsch had the advantage in his cases that the patients came back again and again. About temperature—that should be reduced first by usual means. Raised temperatures were not permanent, and after reduction tuberculin could be suitably used. He had never seen a reaction in a syphilitic patient. That, properly used, it is a test of cure is a corollary to trusting to it for diagnostic purposes. In answer to Dr. Squire, the local lesions are certainly lit up, but as the tuberculin is gone on with, they again clear up and disappear. Of such cases as Dr. Williams described he had had no experience.

Professor Koch, in reply, stated that the tuberculin used so far had been obtained from human sources. The reaction to tuberculin was a simple reaction, not a specific one. There existed many different kinds of tubercle bacilli, but they all gave the common reaction. He spoke very eulogistically of Dr. France's experiments, and said they were a model of what was needed in place of so much theoretical speculation. As to the temperature, patients who were febrile must be put to bed, and the fever reduced by usual means before tuberculin is used. But in many cases of tubercle the temperature was not raised, and no preliminary treatment was needed before beginning with small doses of tuberculin. He believed in open-air treatment and other measures plus tuberculin, not relying on either one or the other but both.

(To be continued.)

Report of a Case in Which a Scarfpin Was Swallowed and Passed per Rectum on the Seventh Day.—Edgar A. Vander Veer reports the case of a man who held a scarf-pin in his mouth, laughed slightly, and sucked the pin into his throat. At first the pin gave great pain, but after a few minutes it seemed to disappear, and the patient could swallow easily. An x-ray photograph of the chest and abdominal cavity showed no trace of the foreign body. The patient was kept under observation and put on a constipating diet, in order to encrust the pin with fæces. His bowels moved every day. On the seventh day he was given a half-grain dose of calomel, and two hours later had a movement of the bowels, when the pin was passed, embedded in the fæces.—*Albany Medical Annals.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 3, 1901:

	Cases.	Deaths.
Measles	127	21
Diphtheria	103	28
Laryngeal Diphtheria (Croup)		
Scarlet fever	130	11
Smallpox	41	14
Chickenpox	6	
Tuberculosis	240	152
Typhoid fever	58	13
Cerebro-spinal meningitis		7

Pneumothorax from Sneezing.—In the *Munchener medicinische Wochenschrift*, some time ago, a case was recorded of pneumothorax occurring in a healthy man from laughing. Professor B. Stiller, of Budapest, now records, in the *Wiener medizinische Wochenschrift*, a case in which this accident was caused by sneezing. The amount of air pumped into the pleural cavity was sufficient to displace the liver. An injection of morphine relieved the pain, which was severe and lasted three days. After a week, all evidence of pneumothorax had disappeared. There was never any pleural effusion. The patient was a young man with perfectly healthy lungs.—*Treatment.*

Insanity in Relation to Creed.—Statistics which concern only small numbers are yet more fallacious than even the general mass of such evidence, still they are sometimes worth examining. During the year 1900, 226 patients were admitted as lunatics into the Bethlem Hospital. From a table which records "religious persuasion" we obtain the following facts, which, let it be noted, however imposing they might seem if cited in an argument, really prove nothing. Of the whole number, 155 were registered as members of the Church of England, and against these only sixty-two were discharged during the year as cured. Thirteen Baptists and thirteen Roman Catholics were admitted, and seven of the former and six of the latter discharged cured. A total of nineteen were ranged under the heads "Congregational," "Dissenter," and "Nonconformist," and of these twelve left cured; of Wesleyans there were seven, and none was cured; of Presbyterians six, and only one was cured. There were two Jews, both women, and one left cured; and the same statement applies to Plymouth Brethren. No "Agnostic" was admitted, but one—an old case—left the hospital uncured. One "freethinker," and two who were registered as "nil," made a small total of three, all of whom left the asylum cured. Quakers are not mentioned, but possibly one woman, who was registered as a "Christian," might be of that persuasion. Thus it will be seen that it might be argued from these facts that members of the Established Church, when they become mentally deranged, are difficult of cure, and Wesleyans yet more so; whilst Baptists, Roman Catholics, Jews, and those of lax creeds fare much better.

Alcoholism in Childhood.—Kassowitz (*Deutsche Medicinal-Zeitung*) concludes as follows: 1. Severe functional disturbances (delirium tremens, alcoholic mania, epilepsy) and organic changes (anasarca, enlargement of the liver) have been observed by the author and others after the continued use of alcohol. 2. These diseases occurred not only after the use of brandy and excessive doses of other alcoholic drinks, but also after the use of ordinary amounts of wine and beer, and even after such small doses of cognac as are usually considered not only harmless but even curative. 3. From these results we must conclude that the nervous system in childhood is extremely sensitive to the poisonous effects of alcohol. 4. The administration of alcoholic drinks to children is

permitted in the best regulated families in the belief that small doses cure weakness and diseased conditions. It is easily demonstrated, however, that this idea is absolutely wrong. 5. Physiological experiments have disproved the former views that alcohol is a food and prevents body waste; the excretion of urea is increased rather than diminished during the administration of alcohol. 6. From this it may be concluded that the protracted use of alcohol prevents the growth and development of the child. 7. Even as an appetizer alcohol is useless, since experiments have shown that it disturbs rather than aids digestion. 8. As an antipyretic alcohol is useless, because even after the administration of very large doses the temperature falls but slightly. 9. Researches have shown that the much-lauded stimulating effect of alcohol either does not occur or is very passing, but that a slow degree of depression of the muscles and nerves takes place. The use of alcohol, therefore, for the prevention and treatment of cardiac weakness in childhood has no scientific foundation. 10. The internal administration of alcohol as an antiseptic—that is, as a bactericidal agent, in acute infectious diseases—is not rational. Experiments have shown that during its administration the resistance against infection is diminished rather than increased, and that alcohol is too quickly oxidized to have any bactericidal power. 11. In school children, even after a moderate use, the weakening effect upon the intellect was evident. 12. From the foregoing ill effects of even moderate amounts of alcohol, the administration of alcoholic drinks to healthy or sick children is under all circumstances to be discountenanced.

An Egyptian Rhinologist and His Reward.—In a volume published from the unfinished manuscript of A. Mariette Bey, entitled "Les Mastabas de l'Ancienne Empire," among many others is a fac-simile of a drawing on a slab found in the tombs of one of the old Egyptian kings. The grave in which the slab was found is said to date back to the fifth dynasty, a matter of 3,500 years before the birth of Christ. On the slab is the delineation of a physician and his wife, the latter with her hand resting affectionately on his shoulder. He was the medical attendant of King Sahura, and his name was Sekhet'enanch, but what the name of his wife was does not appear. It is said to have been everywhere erased from the tablets. What subsequent domestic infelicity this may hint at, we know not. Edward Meyer, in his "Geschichte des alten Aegyptens," translates some of the inscription relating to the physician in such a manner that it appears the king had ordered it to be engraved as a testimony of gratitude to his doctor because he had "made his nostrils well." He wishes him, therefore, long life and happiness. This tablet had formerly been set up in the king's palace, in an ante-room, where all might see and read. We see hereby not only the antiquity of medicine, but also the antiquity of certain propensities which have not yet disappeared, so the uncharitable say, from the activities of its devotees; for we read further in Meyer's text that this method of recompense was suggested to the king by Sekhet'enanch himself. However, it does not appear that this early practitioner of medicine and violator of medical ethics was necessarily a rhinologist, for the word "nose" in this place, according to the translator, seems to have signified "breath of life." This, of course, makes the meaning of the passage very indefinite. It is an indication, however, that five thousand years ago they recognized the nose as belonging to the respiratory system, a fact to which it has frequently been necessary to draw attention in later, and we are fain to believe more enlightened, times.—Dr. JONATHAN WRIGHT, in the *Laryngoscope*.

The Extermination of Rats.—Rats have long been inseparably associated with the plague. Their connection with the outbreak in Glasgow was never conclusively proved, but in India, in Egypt, and latterly in Cape Town, they have been, beyond a doubt, largely instrumental in disseminating the disease. Whenever a plague scare arises, one of the first measures proposed is the destruction of rats, but the thing is a thoroughly complete and effective fashion is more easily proposed than done. More particularly is it difficult on board ship, and yet it is by means of ships that these insufferable rodents carry the disease germs from port to port. A special interest, therefore attaches to the recent experiments at the London docks for the extermination of rats, by means of sulphur dioxide. This gas seems to have the property of attracting the rats from their holes and as soon as they breathe the fumes they become suffocated. At the same time it has no injurious effect on the decorations of the saloon. The experiments were conducted on board the steamship "Gourkha," and were highly successful. Several hundred rats being destroyed in the space of a few minutes. Among those who witnessed the experiments on the "Gourkha" was the Chairman of the Cape Chamber of Commerce, and he is said to have been so much impressed with the efficacy of the new method that he has resolved to recommend its adoption to the Harbor Board at Cape Town with the view of applying it to all vessels coming from plague-infected ports.—*Sanitary Record*.

What to Do with Consumptives.—A novel suggestion as to the disposal of consumptives is made by Sir Henry Littlejohn, Medical Officer of Health for the City of Edinburgh. Commenting on the relative positions of the rich and poor afflicted with the disease, and the power to recuperate often regained in foreign latitudes, he asks whether this luxury cannot be provided for the working and skilled mechanic of England, not to speak of the ordinary laborer. He has often thought, he says, that when the Transvaal quiets down, the local government there might be inclined to receive specially selected lives of skilled workmen suffering from incipient tuberculosis who would not be birds of passage, but would remain as useful, intelligent citizens.—*The Sanitary Record*.

Health Reports.—The following cases of small-pox, yellow fever, cholera and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 3, 1901:

SYPHILIS OF THE LIVER.*

BY MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

IT seems, at the first glance, hardly necessary to write about an affection which is so well known and which in its essential features had already been described in the middle of the nineteenth century. Looking through the literature, however, it is apparent that clinically not so much has been published on this subject as its practical importance would warrant. I will therefore briefly review the literature, then present my own observations on syphilis of the liver, and finally add a few remarks.

From the middle ages to the beginning of the seventeenth century great importance was attached to the liver in syphilitic diseases. It was generally believed that syphilitic ulcers were the result of bad humors of the body, the origin of which was to be looked for in the liver, which was supposed to be infected by a volatile contagion (Fallopia[1]). When pathological anatomy began to be studied more closely, the theory of the primary affection of the liver in syphilis was discarded by Botalli, Petronius, Mercurialis,[2] and others. For a long time thereafter syphilitic disease of the liver was not even mentioned.

Bonet,[3] Portal,[4] and Ricord[5] were the first to demonstrate syphilitic changes in the liver. Ricord was the first to use the term gummatous tumor. Dittrich[6] soon after wrote a comprehensive paper on syphilitic disease of the liver. I will cite from Dittrich's fundamental work the following passage: "The participation of the liver in syphilis consists in various processes of inflammatory exudation; these usually heal either completely or incompletely, leaving behind a cicatrix. The process of exudation never affects the whole liver, but mostly a few separate places." The origin of deep scars and furrows (even lobulation) of the liver was in this way plausibly explained by this writer.

Dittrich's paper was soon followed by a thorough and extensive article by Gubler,[7] who wrote on syphilitic changes of the liver in childhood, caused by hereditary syphilis.

Virchow,[8] the master of modern pathology, next published an important work, in which, among other topics, syphilis of the liver was thoroughly treated. I would like to cite the following passages: "The products of syphilis are indeed just as diverse in the liver as in the testicles. We may have a perihepatitis, a plain or a gummatous interstitial hepatitis. All three may be present at the same time, complicating one another. In the majority of cases, we have a plain interstitial hepatitis and only in some special instances a gummatous." Concerning the nodules, Virchow says: "The result of microscopic examination has been correctly stated by Budd. Usually we find, just as in the tuberculous nodule, nothing but a dense mass inside, full of fine fat granules, in which some nuclei, perhaps also cells or granular bodies and connective tissue fibres, may be more or less clearly distinguished." The capsule or scar tissue enveloping the nodule gradually and continuously merges into the substance of same: "The nodule is only a part of the scar tissue that has undergone more advanced changes. Concerning, finally, the chronology of syphilitic hepatitis we are in many respects justified in grouping it among the tertiary symptoms. It is, however, certain that simple induration and atrophy with cicatricial formation may occur in hereditary syphilis in connection with fresh secondary lesions."

In his well-known book on "Diseases of the Liver" the great clinician Frerichs[9] gives a detailed description of syphilis of the liver, citing several cases in which the diagnosis has been made during life. We quote the following passages: "Syphilis of the liver occurs in three varieties: first, simple interstitial hepatitis and perihepatitis; second, gummatous hepatitis; third, waxy, amyloid, or lardaceous degeneration of the liver. All three forms can be present at the same time or each may occur by itself. In the gummatous form of syphilitic hepatitis we observe in the scar tissue just described white or yellowish nodules of round form and dry consistence; they are usually no larger than a lentil or a bean, but may reach the circumference of a walnut. The node cannot be enucleated, as it is traversed by connective tissue masses; it consists of fat drops and fat granules, nuclei, fat cells, and connective tissue shreds. It corresponds, accordingly, with the gumma found in constitutional syphilis, in the subcutaneous cellular tissue, under the periosteum, in the testicles, etc."

Concerning the symptoms of syphilis of the liver, Frerichs expresses himself as follows: "The most constant of them are pains in the region of the liver, sometimes confined to certain places, sometimes extending over the whole organ. They are, as a rule, dull, sometimes, however, acute enough to cause considerable trouble. The pains may be of long duration; one of my patients complained for three months; in another there were intermissions lasting several weeks with subsequent exacerbations, accompanied by a slight fever."

Frerichs acknowledges the difficulty of diagnosis in the following words: "The differential diagnosis between syphilis and carcinoma of the liver is sometimes very difficult, because the principal symptoms of the latter disease, hard, painful nodular tumors of the liver, may also occur in syphilitic disease of this organ, provided we have a process of waxy infiltration (if the latter is not present, the protuberances are much softer than in cancer). The presence of constitutional syphilis, the intermittent pain, the enlargement of the spleen, and the albuminuria may lead us on the right track."

Soon after the publication of Frerichs' book there appeared several reports of cases of syphilis of the liver, mostly from an anatomical and pathological standpoint.

Thus Wilks[10] describes several observations of his own on syphilis of the liver (mostly autopsies).

*Read before the American Gastro-Enterological Association, on May 1, 1901, at Washington, D. C.

J. F. Payne relates three cases of gummatous tumor of the liver, all in men. The diagnosis was made on the post-mortem table. Payne describes the tumors microscopically as follows: "The central parts of each tumor were composed of granular, almost amorphous material, not fibrous, though sometimes with indistinct fibrillation. There were in these parts hardly any nuclear or cell forms. The only structures which seem characteristic were certain round or irregular translucent bodies, of the size of several lymph cells, which were imbedded in the granular mass. It seemed probable that these masses represented collections of degenerated liver cells. There were also very numerous fine granules of fat, but any distinct or larger drops were not present. The granular portions passed imperceptibly into fibronucleated structure, which formed a transition to the external fibrous tissue, but was not universal or characteristic."

W. Pepper[12] found gummata in the liver and in the brain at the autopsy of a woman, who had suffered from a left-sided hemiplegia and a right-sided paralysis of the oculomotorius and abducens nerves.

Norris[13] published a case of gumma of the liver, which had caused an occlusion of the gall ducts, and was recognized only at the autopsy.

About ten years later an important article on this subject was published by L. Peiser,[14] of New York. This author carefully observed a case of syphilis of the liver which came to a post-mortem, and collected from the literature histories of thirty-three cases of this disease. Among these thirty-four cases twenty-one were in men and thirteen in women. The time that had elapsed since infection could be determined in only fifteen cases; usually it ranged from three to seven years; the shortest time was three and a half months, the longest, twenty-five years. The most constant symptom was pain, sometimes localized, sometimes diffused, sharp or dull; sometimes only tenderness on pressure was present. Usually associated with this were disturbances of the stomach and bowel functions. When marked changes of the liver existed, ascites and anasarca occurred; enlargement of the spleen was more often caused by direct syphilitic disease than by a congestion of the portal system. Icterus occurred twelve times. Cachexia and albuminuria were frequently found. Of the thirty-four patients twenty-nine died, two were cured, and three improved.

After Peiser's work several observations of a more clinical nature on syphilis of the liver were recorded. Thus, Osler[15] describes two cases in which a cure took place. He says: "For two years, I showed repeatedly, at my clinic at the University Hospital, Philadelphia, a boy aged eleven, who had a prominent tumor in the epigastrium connected with the liver, the nature of which was obscure until well-marked bone lesions developed. In another case, a man aged thirty was sent to me for advice concerning the making of an exploratory incision to determine the nature of a firm, irregular tumor, which occupied the epigastric region and was evidently connected with the left lobe of the liver. It had lasted for more than a year, had increased slightly, and had not impaired, to any marked degree, the general health. This fact, together with a well-marked history of acquired syphilis, led me to place him upon a rigid antisyphilitic treatment, with the result that within six months the entire tumor disappeared."

Cole[16] describes two cases of syphilitic cirrhosis of the liver. In both he had to deal with an enlarged liver with marked ascites; one of the patients gave a distinct syphilitic history. Both were cured after taking iodide of potassium and mercurial inunctions for a long time.

De Walsche[17] reported a case of syphilitic hepatitis. The subject was a fourteen-year-old boy, who, for a year, had been suffering from a pain in the region of the stomach. He was somewhat icteric. On examination the liver was found to be much enlarged and somewhat harder than normally; there were no nodes, but the organ was especially tender on pressure. The fæces were acholic, but contained no gall-stones. The usual treatment for icterus was without result. De Walsche then, by exclusion, made the diagnosis of syphilis of the liver. Antiluetic treatment was promptly followed by a cure.

Lancereaux[18] has contributed several important works on syphilis of the liver. I quote from his book on diseases of the liver the following passages: "If this organ is enlarged and cirrhotic, it gives on palpation a sensation of manifest hardness, of an uneven, embossed surface; in the gummatous form, we feel protuberances, or rather firm nodules, sharply circumscribed or disseminated through the whole organ. On account of the great frequency of perihepatitis, it is rare for patients not to complain of pain, more or less acute, occurring in the right hypochondrium. The pain manifests itself sometimes merely as an uncomfortable sensation, as malaise, or a feeling of weight; sometimes it is continuous, with sharp exacerbations. It is nearly always increased by palpation, percussion, and especially by movements of the thorax, and radiates toward the shoulder or some other part of the body."

J. Marcuse[19] endeavors to define the clinical picture of syphilis of the liver, although he is conscious of the difficulty of the task. He says: "However exact the pathological investigations may be, and however easy it is to make the diagnosis of syphilis of the liver on the post-mortem table, just as difficult is it to make a correct clinical diagnosis during life. Even in cases in which the autopsy revealed deep scars and numerous gummata, the syphilitic hepatitis had caused such insignificant symptoms during life that it was impossible to make a diagnosis. Added to this is the variety of clinical as well as pathologico-anatomical forms of the disease, which contribute to the difficulty of diagnosis." "Icterus in the tertiary period is extremely rare; if it does occur it is due to compression of the gall ducts by gummata, or to glandular swellings at the hilus of the liver, etc." . . . "The skin of most patients is of a dirty, pale, ashen color. Lancereaux often found brown pigmentation."

Leichtenstern[20] also expresses himself in a similar manner: "Large isolated gummata of the liver can, in rare cases, also be diagnosed if with a history of syphilis, especially congenital syphilis of children, and perhaps in the presence of gummata of the skin or bones, a firm, round tumor plainly projects from the anterior surface of the liver near the suspensory ligament, the favorite location of gummata. It is plain that under such circumstances, in a similar case, a faulty diagnosis of carcinoma may be made."

Waring[21] attempts to establish the differential diagnosis in the following words: "The liver may attain a considerable size as a result of the development of these tumors, and then it resembles in many respects a liver which has been enlarged owing to the formation of numerous primary or secondary malignant growths. The rate of increase in size of the organ is, however, much slower in syphilitic affections than is the case in malignant disease, whilst there is not the same marked wasting cachexia."

Adami[22] protests against the strict classification of the various stages of syphilis; according to him the process is, taken all in all, the same. He expresses himself as follows: "In three out of eight cases of tertiary syphilis affecting the liver which have come to the post-mortem room at the Royal Victoria Hos-

pital during the last four years, there was clear and fairly extensive pericellular fibrosis along with gummatous change. The fibrosis, it is true, was not generalized over the whole liver. The condition more resembled a condition of circumscribed fibroid change seen in the infantile liver."

Semmola and Gioffredi[23] have discussed the important question whether a visible secondary syphilitic lesion must of necessity always have preceded syphilis of the liver, in the following words: "There has been, and still is, much discussion as to whether syphilitic infection can be long latent without causing secondary phenomena, and can then later attack the liver. Our clinical experience is in harmony with the ideas expressed by Cardarelli that whether there be an actual absence of symptoms of general infection, or whether they be so light in character as to pass unnoticed, the fact remains, and is of great diagnostic importance, that some patients have a syphilitic liver without giving any history of secondary phenomena of the disease." Regarding the frequency of syphilis of the liver these authors express themselves as follows: "We are not to understand, however, that among the tertiary symptoms of syphilis those relating to the liver are of very frequent occurrence. In Fournier's statistics, which are the most complete which we as yet possess, we find that in 3,429 cases of tertiary syphilis there were nine of hepatic syphilis. We must, however, bear in mind that syphilis of the liver may run a latent course, or may be confounded with other hepatic affections."

According to Birch-Hirschfeld,[24] syphilis of the liver in reality seems to occur quite frequently. He says in his book: "The gummatous affections of internal organs (visceral syphilis) develop most frequently in the liver, the testicles, the spleen, the brain, more rarely in the lung, the spinal cord, the kidneys and suprarenal glands, and the pancreas."

Having cited from the principal works on syphilis of the liver accessible in literature, I now pass on to some of my own observations. As I have not had occasion to see a case of hereditary syphilis of the liver I will confine myself to hepatic affections caused by tertiary syphilis.

Cases of syphilis of the liver can conveniently be divided into the following groups:

1. Gummata of the liver. 2. Syphilitic cirrhosis of the liver. 3. Syphilitic disease of the liver belonging to either of the above groups and accompanied with icterus; the latter may be: *a*. Acute, *b*. Chronic.

The following cases belong to Group 1 (*gummata of the liver*):

Case I.—April 19, 1900. Harris S., thirty-four years old, had a chancre six years ago. He had always been well and strong until the spring of 1897, when he began to complain of various disturbances of digestion. He had a poor appetite and suffered from nausea occasionally, although rarely. He also complained of much belching and frequently had severe pains a short time after eating. His sleep was restless. He was constipated and felt very weak and miserable. He had lost twenty-three pounds. He came to me on August 24, 1897. I found at that time a distinct resistance in the gastric region; the tumor was somewhat uneven, of about the size of a dollar, and was situated near the lesser curvature. The liver was not enlarged. August 31, 1897, the patient again called on me. His condition was the same. An examination of the stomach contents showed the presence of free hydrochloric acid and no ischochymia. In spite of the favorable result of the chemical analysis, I thought that I had to deal most probably with a case of carcinoma of the stomach. As there was a history of syphilis, however, and thinking of the possibility of a syphilitic tumor of the stomach, I gave the patient potassium iodide, 3.0:200.0, a tablespoonful three times daily.

I then had no further opportunity to see the patient until April 19, 1900. On this day he called at my office again, saying that the medicine at the time had helped him, that he had taken it for three months and had become perfectly cured. He also had gained his former weight. Within the last two months, however, he had again begun to suffer from pains in the right side and a sensation of pressure and tension in the abdomen. His appetite was not very good, and his bowels were irregular. He had again lost seventeen pounds in weight. At the examination I found an immense tumor of the liver, which extended to one finger below the umbilicus and reached from the left to the right mammillary lines. The swelling was of a rather firm consistency, and presented in the surface numerous knobs varying in size from that of a walnut to that of an apple. The tumor could be traced directly into the liver (Fig. 1). The upper border of the liver dulness was at the normal place. The organ was but slightly sensitive to pressure.

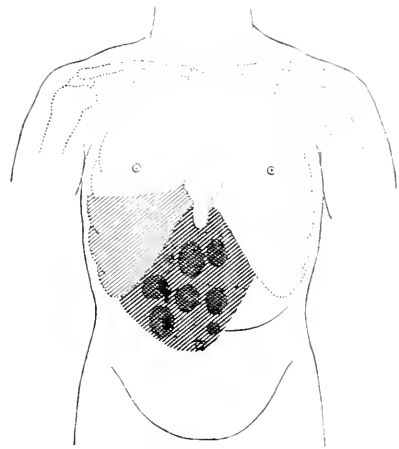

Fig. 1.—Harris S.

The stomach at this time did not present anything abnormal. The spleen was not markedly enlarged.

Knowing the previous history of the patient, I this time made a diagnosis of a large syphilitic tumor of the liver and instituted a systematic antiluetic treatment (inunctions of mercury and internal administration of potassium iodide). I presented the patient at that time in my clinic at the New York Post-Graduate Medical School, and we could note, from week to week, the diminution in the size of the tumor. After six weeks there was nothing left of the mass which had originally filled the upper half of the abdomen, the liver having returned to its normal size. The patient felt well, gained in weight, and has not been ill since.

Case II.—May, 1898. Samuel G., forty years old, had a chancre ten years ago. He had always been healthy until about six months ago, when he began to suffer periodically from violent attacks of pain in the region of the stomach. These usually occurred suddenly. The pain was very intense and was specially felt in the epigastrium, and, as a rule, one or two morphine injections had to be given before relief was afforded. While at first these attacks occurred once a month, they now come nearly every week. During the interval the patient feels quite well; his appetite, however, is diminished, and his bowels are

constipated. In the last six months he has lost over thirty pounds.

He first consulted me in the middle of May, 1898. I found the following conditions at that time: On the forehead is an exostosis of the size of a dollar and a half centimeter in thickness. In the abdomen, directly under the ensiform process, lies a somewhat nodular tumor of the size of a big apple, extending to

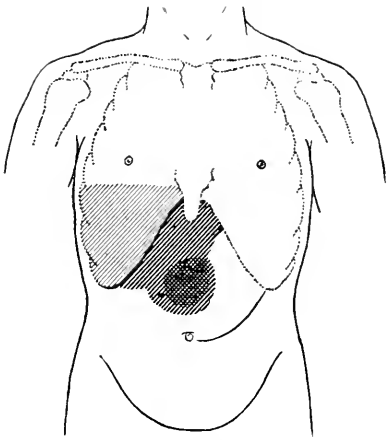

Fig. 2.—Samuel G.

within two fingers' breadth of the umbilicus. It moves up and down with the liver and seems to originate from its left lobe. The right lobe of the liver does not seem especially enlarged (Fig. 2). In the stomach nothing abnormal is to be found. The diagnosis fluctuated between gallstones, carcinoma, and gumma of the liver. I soon decided in favor of the latter, the more readily on account of the presence of

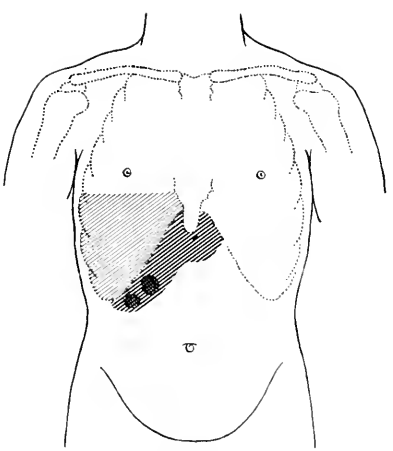

Fig. 3.—Joseph D.

the exostosis on the frontal bone. My colleague, Dr. D. Froelich, the family physician of the patient, agreed with my diagnosis. Antisyphilitic treatment (mercury inunctions and potassium iodide) was begun and in the course of a month we had the pleasure of seeing the tumor of the liver disappear and the bony swelling on the forehead diminish in size. The patient felt very much better and remained free from attacks for about six months.

He afterward again became ill, and was treated by other physicians, so that neither Dr. Froelich nor I had the opportunity to watch the further course of the disease. He died in the spring of 1899.

Case III.—June, 1897. Joseph D., forty years old, acquired syphilis eight years ago, and was treated for it. In the last three years he frequently complained of various stomach troubles (eructation, capricious appetite, feeling of fulness after meals) and of rather intense pains, occurring occasionally on the right side (region of the liver). He has lately also suffered repeatedly from severe diarrhœa. With this history and the statement that he had used alcohol freely, the patient consulted me in June, 1897.

On physical examination the liver was found considerably enlarged, reaching in the right mammillary line two fingers' width below the margin of the ribs. It was of firm consistency and showed on its anterior surface, directly over its free edge, two round tumors of about the size of a walnut, which were immovable and closely connected with the liver (Fig. 3). The patient looked well nourished, and had not lost much in weight. Otherwise nothing abnormal could be discovered. Enlargement of the spleen was not

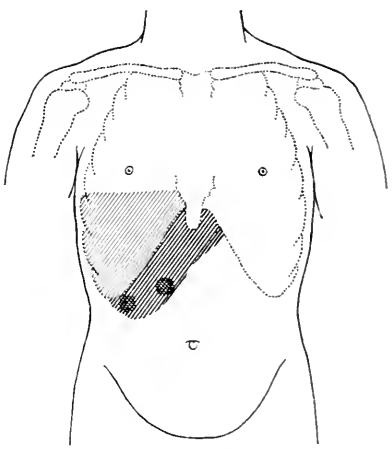

Fig. 4.—Abraham F.

marked, and the urine was free from albumin and sugar.

In the diagnosis of this case the conditions to be considered were: cirrhosis of the liver, malignant neoplasm, syphilitic diffuse enlargement of the liver with gummata. The presence of the nodules argued against pure cirrhosis; the considerable enlargement, the absence of marked cachexia, and the history were opposed to the theory of carcinoma. Therefore syphilis of the liver was diagnosed. Treatment with iodide of potassium quickly improved the subjective symptoms, the two tumors disappeared, while the organ itself remained considerably enlarged. The patient is at present (four years later) perfectly well.

Case IV. July, 1899. Abraham F., twenty-six years old, has complained for three months of tension in the upper part of the abdomen and frequently recurring pains in the region of the liver. His appetite lately has been capricious, his bowels are inclined to be constipated, and his sleep is restless. He feels weak, and has also lost in weight (about ten to fifteen pounds). He never had a chancre, but had gonorrhœa about five years ago. He does not drink or smoke.

Physical examination revealed a tumor of the liver. This organ was considerably enlarged downwards,

extending in the right mammillary line three fingers' breadth below the margins of the ribs. It felt hard and uneven and presented two rather firm nodes, about the size of a hen's egg, situated over the margin of the right lobe (Fig. 4). The other organs were normal; the spleen was not enlarged, the urine was free from albumin and sugar.

The result of the physical examination of the liver seemed to point to a malignant neoplasm. The youth of the patient, however, and his comparatively slight symptoms were against cancer. Although, according to his statement, he had never had syphilis, yet I could not altogether exclude the possibility of a luetic affection of the liver. He received two grams of iodide of potassium daily, and was told to continue its use for a long time. In the beginning of September, 1899, I had occasion to re-examine this patient. A tumor could no longer be discovered and the liver itself reached only slightly below the right margin of the ribs. He told me that he had gained twenty pounds since beginning the treatment, and that he had now no trouble whatsoever.

To the second group, *syphilitic cirrhosis of the liver*, belong the following cases:

Case V.—October, 1900. Henry H., forty-six years, has always indulged in the use of alcohol very moderately. He had a chancre ten years ago. During the last three months the patient has suffered almost constantly from pains in the region of the stomach, loss of appetite, and constipation, together with a certain stiffness in the joints. He lost during this time about twelve pounds. On examination the liver (especially the left lobe) in its whole extent was found enlarged and harder than normal; distinct nodules could not be felt. Otherwise nothing abnormal was found. A slight enlargement of the spleen was present; the urine was free from albumin and sugar. Since an abuse of alcohol was not present, the cirrhotic enlargement could with all probability be attributed to syphilis, the more so since the man gave a history of that disease. The patient was treated with iodide of potassium, and rapidly improved.

Two patients whom I observed in the German Dispensary also belong in this class. They were both men of about thirty-three to forty years, with an enormously enlarged liver without nodules. Both gave a clear history of syphilis, besides having gummata of the bones (the one of the manubrium sterni and body of the sternum, the other of the thoracic vertebræ). Under antisyphilitic treatment these osseous gummata disappeared in both, the volume of the liver became smaller, and the pains ceased.

To the third group, *syphilitic affections of the liver with* (a) *acute* and (b) *chronic icterus*, belong the following cases:

Case VI.—March, 1896. Martin S., thirty-six years old, had been always healthy with the exception of a chancre which he acquired six years ago, and which was at that time thoroughly treated. In March, 1896, the patient consulted me for the first time. He said that for a few weeks he had had a poor appetite, that he felt bloated after his meals, that he had a bad taste in his mouth, and was inclined to be constipated. His sleep was somewhat restless, and he had lost strength. A week later he had a severe attack of pain, which was felt in the epigastrium and the whole region of the liver, and was accompanied by a rise of temperature to 103° F.

On examination the liver was found swollen and tender on pressure. The skin was of a light icteric color. The urine contained bile pigment, but the fæces were acholic. Opiates relieved this pain. During the next three days the rise of temperature continued, and his body became jaundiced. Under the use of Carlsbad water the icterus began to disappear, and after two weeks his skin was very nearly free from jaundice. A thorough examination of the fæces for gallstones was negative in its results.

The patient felt very much better after this treatment, and was again able to attend to business. He suffered, however, every day for a short while from pains in the right hypochondrium. At a second examination the liver was found considerably enlarged, projecting about three fingers' width beyond the right border of the ribs; the organ felt somewhat hard and presented a nodular tumor of about the size of a pigeon's egg a little to the right of the linea alba (Fig. 5). The spleen also was much enlarged, and could plainly be palpated under the left margin of the ribs, being also somewhat harder than normal. There

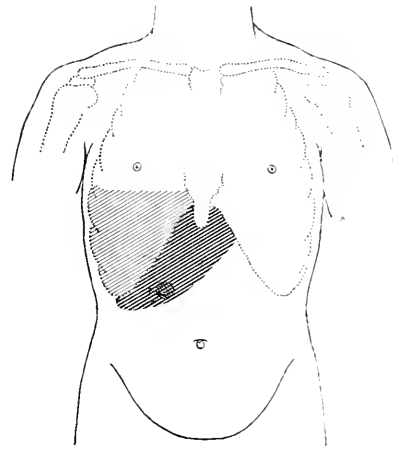

Fig. 5.—Martin S.

was no ascites. Considering his history, the rapid development of nodules in the liver, and the swelling of the spleen, the diagnosis of syphilis of the liver seemed justified. Antisyphilitic treatment (inunctions with mercury, and iodide of potassium internally) soon brought relief. The pains stopped, his strength returned, and the nodules in the liver disappeared; the volume of the liver also diminished considerably. The patient has remained perfectly well since.

Case VII.—November 15, 1899. Jacob A., thirty-nine years old, had syphilis in his youth. For three months he has complained of attacks of pain in the right half of the abdomen, accompanied by obstinate constipation. Five days ago he took ill with severe pains on his right side. He had absolute loss of appetite and slight chills. His family physician made a diagnosis of appendicitis. I was consulted that day, and found on examination slight jaundice and a marked swelling of the liver (the lower border of which reached two fingers' width below the right margin of the ribs), and great tenderness of this organ. The abdomen was somewhat tympanitic, but real signs of appendicitis were not present. The pulse was 100, temperature 102° F. I made a diagnosis at that time of an hepatic disturbance accompanied by icterus, caused perhaps by gallstones. The patient received sodium bicarbonate with glycerin, was placed on a strictly fluid diet, and treated with oil enemata. His condition soon improved, the fever abated, the pains disappeared, the appetite returned, and his skin resumed its normal color. Although the fæces were always examined for gallstones none was found.

The patient again consulted me in January, 1900, saying that since his last attack he had been quite well, but that he suffered much from constipation. Physical examination of the abdomen showed an enlargement of the liver; hard or uneven places, however, could not be discovered in this organ. He received podophyllin 0.01 gram twice a day. In May, 1900, he again consulted me, principally on account of frequently recurring pains in the right

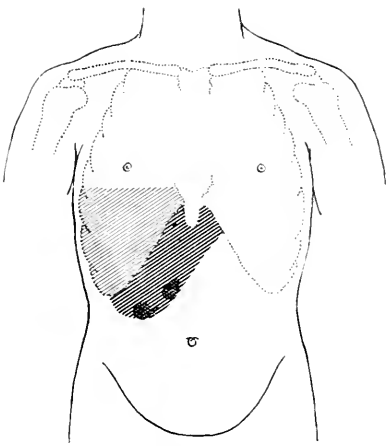

Fig. 6.—Jacob A.

hypochondriac region; he had also lost fifteen pounds lately.

Examination of the liver now revealed that in the right mammillary line it reached three fingers' width below the margin of the ribs. The upper boundary of the organ was at its normal level. At the lower border of the liver there were two firm nodes of the size of a hazelnut (Fig. 6). The consistency of the liver as a whole was somewhat firmer than normal. In consideration of his previous history, a diagnosis of syphilis of the liver was made, and the jaundice above described was attributed to this cause. Under the use of iodide of potassium for about three months the patient recovered perfectly; the nodules in the liver and the pains disappeared, but a slight enlargement of the organ remained.

Case VIII.—August, 1900. Mrs. Minna M., thirty-seven years old, suffered when a child from "stomach cramps," but later had been always well. Eleven years ago she married. She had two children, and an abortion at four months six years ago. Her last child was born March, 1900. Four weeks before confinement she had severe pains on the right side followed by an intense jaundice. She has complained ever since of pains in the region of the liver, and remained jaundiced. Her weight decreased from 135 to 108 pounds, and she felt weak and miserable. In August, 1900, she came to me with the above complaints. She did not present any symptoms pointing distinctly to syphilis. She maintained that she never had had an eruption, that her two living children were perfectly well, and that her husband had never had any disease. The only sign pointing to the possibility of a luetic affection was the abortion and the statement that her hair was falling out.

The thoracic organs were normal. Palpation of the abdomen revealed an enormously enlarged liver, reaching down to the navel. The organ was considerably harder than normal, and showed on its surface several nodes each the size of a walnut. In the right lobe a furrow could be felt at the lower edge in the mammillary line (Fig. 7). Percussion showed that the liver dulness began in the fifth intercostal space. It was therefore a real enlargement and not a ptosis of the organ. The liver was rather tender on pressure. The stomach extended to the navel and was not particularly sensitive to pressure. The skin of the whole body was very much jaundiced. The color of the lips and cheeks was pale. The fæces were clay-colored, and the urine contained bile pigments in large amounts.

When I saw the patient for the first time, I could not positively decide whether there was a malignant neoplasm or a syphilitic affection of the liver. Therapeutically the administration of potassium iodide was justified. The patient received two grams of the drug daily and soon began to feel better. The pains disappeared, and the icterus after a while began to diminish. In the middle of January, 1901, the patient had hardly any icterus. She had a good appetite, felt stronger, and had even gained in weight. Now, I made a positive diagnosis of hepatic syphilis. On March 17, 1901, she had gained ten pounds in weight, felt well in every way, and was able to attend to her regular duties. The skin showed traces of a jaundiced appearance, but the urine was free from bile. The examination of the liver showed a slight diminution in size, as well as a somewhat softer consistency; the nodules had also become smaller. The result of a blood examination was as follows: hæmoglobin, eighty-seven per cent.; red blood cells, 5,120,000; white blood cells, 6,500.

A differential count of 500 leucocytes showed:

Polymorphonuclear	33.4	per cent.
Small lymphocytes	45	" "
Large lymphocytes	8.2	" "
Eosinophiles	9.8	" "
Transitional	2.8	" "
Mastcells	0.8	" "

The considerable increase of eosinophiles (nearly ten per cent.) and lymphocytes (over 50 per cent.)

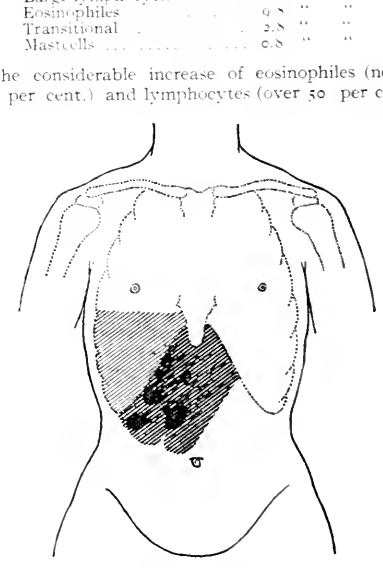

Fig. 7.—Mrs. Minna M.

would, according to the investigations of several authors (Neusser, Cabot), also speak for syphilis.

Case IX.—October, 1899. Mrs. Martha N., sixty years old, had been suffering about a year from frequently recurring pains in the right hypochondrium and from jaundice. Her appetite was poor. She had belching, but no vomiting, and her bowels were inclined to be constipated. She never indulged in alcohol. She had had several children and two abortions, but nothing otherwise pointed to syphilis.

During the last year she had lost forty-five pounds in weight and felt exceedingly weak and miserable. She was hardly able to walk a few paces.

On examination the following condition was found: The patient is much emaciated, skin yellowish-green, color of cheeks and mucous membranes pale, tongue heavily coated. The thoracic organs show nothing abnormal. The liver dulness begins in the mammillary line in the fifth intercostal space and reaches down

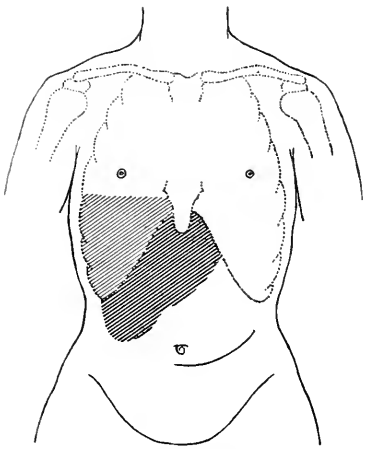

Fig. 8.—Mrs. Martha N.

to a level with the navel; in the middle line, however, the dulness terminates three fingers' width above the navel (Fig. 8). Palpation gives the same boundaries for the organ. The latter feels somewhat harder than normal, but presents no nodules. The stomach reaches two fingers' width below the navel. The urine contains much bile pigment, but neither albumin nor sugar. The fæces are acholic.

The patient was treated for a time with Carlsbad salts and later with glycerin, but without much success. I then concluded to try iodide of potassium. After the use of this drug her condition improved from week to week. The icteric tint of the skin became much less marked, the bile pigment disappeared from the urine, the patient steadily gained in weight and felt stronger. The swelling of the liver also became less, although it never disappeared altogether. This improvement could be followed by me for a whole year, when I lost sight of the patient.

Case X.—March 1, 1901. Benjamin Z., forty-one years old, had syphilis when a young man of seventeen years. He has been well since, up to within one and one-half years, when he experienced severe pains in the region of the liver and became jaundiced. The jaundice has persisted, although it is less at times. His pains have never left him. He lost fifty pounds in weight. He does not drink, and smokes but little.

Status præsens: skin jaundiced, of a brownish tint, lips and cheeks pale, tongue not coated. The thoracic organs appear normal. On palpation of the abdomen a considerable enlargement of the liver can be made out. This organ feels somewhat harder than normal, but presents no distinct nodules (Fig. 9). There is some tenderness on pressure. Examination of stomach and bowel gives negative results. The urine contains much bile pigment, but neither albumin nor sugar; the stools are acholic.

Syphilis of the liver was suspected, and the patient treated accordingly, receiving three grams of iodide of potassium daily. Two weeks later he reported that during the last week he felt no more pains in the liver. His skin was much less jaundiced, the urine no longer contained bile, and the fæces had assumed a normal dark-brown appearance.

In connection with the cases described above, it may be of advantage to discuss the principal points of symptomatology, diagnosis, prognosis, and treatment of syphilis of the liver.

Symptomatology.—In the majority of cases of syphilis of the liver, pains in the right hypochondrium are present, sometimes constantly, sometimes in the form of attacks; in the latter case they usually are of a very severe character, occasionally much resembling gallstone colic.

Various disturbances of digestion, as lack of appetite, frequent eructations, bad taste in the mouth, constipation, much more rarely diarrhœa, are found in nearly every case of this affection. We often meet with a feeling of tension in the upper half of the abdomen. General malaise, restless sleep, moroseness, weakness, etc., are also frequently present. If the affection of the liver has been in existence for some time, the patients usually lose in weight, but never to such an extent as in malignant neoplasms of this organ.

Icterus may be acute, persisting for a short time and then disappearing, or it may become chronic. In the first case we have either a variety of catarrhal icterus accompanying the syphilitic process in the liver or a gumma temporarily compressing the hepatic duct. In chronic icterus there is either a narrowing of the hepatic duct by gummatous tumors or scar tissue, or the connective tissue proliferation involves more especially the biliary ducts of the liver. The color of the skin in most patients, except those suffering from icterus, is not changed. It is only in the later stages of the disease that an ashen or light-brown discoloration of the skin is observed.

No matter to which of the above-mentioned groups the morbid process in the liver belongs, the organ is

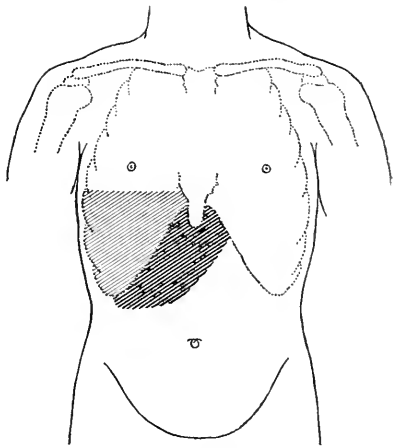

Fig. 9.—Benjamin Z.

usually found more or less swollen, extending in the right mammillary line beyond the free border of the ribs. If gummata are present they may frequently be recognized as somewhat uneven, round, hard nodules on the surface of the liver. If there is a cirrhotic process due to syphilis, a marked swelling of the organ is encountered. In the more advanced stages of syphilis of the liver, amyloid degeneration appears. The organ, then, presents a harder and smoother appearance than normally.

Enlargement of the spleen was not of constant

occurrence in my cases. Ascites may develop in a late stage of the disease. In none of the cases described above had this stage been reached.

Diagnosis.—The diagnosis of hepatic syphilis can be most positively made in cases in which there exist gummata of the liver, together with other signs of a present or recent attack of syphilis (Cases I, II). The diagnosis is more difficult when we find tumors of the liver in persons without other signs of existing syphilitic processes, and either with or without a history of previous syphilitic infection (Cases III, IV, VI, VII, VIII). In these cases the question whether we have to deal with syphilis of the liver can be decided only after observing the effect of antiluetic treatment. If the tumor diminishes or disappears and the symptoms at the same time improve we have to deal with gummatous tumors.

The diagnosis is less certain in cases in which there is simply an enlarged, somewhat indurated liver, with or without icterus, but without gummata (Cases V, IX, X). In these cases the diagnosis, even under the most favorable circumstances—*i. e.*, history of previous syphilitic infection, presence of bony tumors, success of antiluetic treatment—can be made during life with some degree of probability, but never with absolute certainty. For syphilitic cirrhosis of the liver resembles so much the ordinary hypertrophic cirrhosis that clinically they can hardly be distinguished. The latter form also is often much benefited by the use of iodide of potassium, although to a less degree than the syphilitic variety.

Differential Diagnosis.—Gummata of the liver are easily confounded with malignant neoplasms. Regarding the degree of resistance found in these two diseases I believe that it is hardly of sufficiently different character to aid us in the diagnosis. We must therefore look for other points. If the disease has lasted for some time (one and one-half to two years or more); if there exist syphilitic manifestations, and if there has been no considerable loss of weight, the resistance encountered in the liver may be looked upon as in all probability syphilitic.

On the other hand, a slow, steadily progressing affection of the liver, without periods of comparative well being, with considerable loss of strength and weight, together with the presence of a neoplasm in the digestive tract (œsophagus, stomach, bowel) would speak for the malignant nature of the neoplasm.

An increase of eosinophile cells in the blood according to Neusser points to syphilis. A disappearance of the tumor after a tentative antiluetic treatment argues most positively in favor of gumma.

Diffuse syphilitic enlargement of the liver may easily be confounded with hypertrophic cirrhosis induced by the abuse of alcohol. In the first case there is usually a history of syphilis. At the same time other syphilitic manifestations are frequently present in the body. Icterus is often met with, and a considerable enlargement of the spleen may already be present at an early period. Antiluetic treatment has a prompt effect.

If, however, we have to do with a simple hypertrophic cirrhosis of the liver caused by alcohol, there is ordinarily a history of the abuse of alcohol and perhaps also of tobacco. Frequently an alcoholic gastritis is present. Moreover, the enlargement of the spleen occurs much later and icterus seems to be rarer. Iodide of potassium, it is true, sometimes exerts a favorable influence in this affection also, but not to such a degree as in syphilis.

Prognosis.—According to most references in literature it seems at first sight as though the prognosis of hepatic syphilis was rather grave. Thus Peiser, whom I have mentioned before, gives twenty-nine deaths among thirty-four cases. Most of the cases of syphilis of the liver, however, that have been published were in the final stages of the disease (ascites, etc.), and were no longer amenable to any treatment. If, however, the diagnosis is made at a stage of the disease when the patient has not lost too much strength and when grave symptoms (ascites, albuminuria, etc.) have not yet occurred, the prognosis according to my experience is very favorable. Of the ten cases above detailed only one patient died, and even this one had been considerably benefited for five or six months, whereas all the others were either perfectly cured or much improved.

Treatment.—The principle of treatment of luetic affections of the liver consists in the measures directed against syphilis. Iodide of potassium or iodide of sodium and similar preparations of iodine play an important rôle. At first two to three grams of the potassium salt are given daily, the amount being gradually increased to five or six grams. Larger doses I have seldom used.

Although in some cases potassium iodide alone may produce the desired result, yet I have seen the best results from the combined use of this drug with inunctions of mercury (ung. hydrarg. 2.0 daily). The antiluetic treatment should be continued for a long time (two to three months and longer).

Beside the specific treatment attention must be paid to the following points: when icterus is present, glycerin (one teaspoonful t. i. d. half an hour before meals) has usually been of great service to me. In the presence of an anæmic condition, iron or arsenic with iron is indicated. Marked ascites may have to be relieved by puncture. In the same manner any other complications present must be treated *lege artis*.

Proper dietetic and hygienic management is also essential. The patient should sleep in a large, well-ventilated room, and be much in the open air during the day. The diet should be bland, but should contain a sufficient amount of nutritive substances. All alcoholic beverages must be forbidden, also the use of strong tea or coffee. Milk and milk soups (gruels), eggs, bread, vegetables, and stewed fruits should be freely given, whereas meats should be taken only in small quantities and not too often.

PREGNANCY FOLLOWING MYOMECTOMY.*

By JAMES N. WEST, M.D.,

NEW YORK.

ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL; ADJUNCT PROFESSOR OF DISEASES OF WOMEN, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

By way of preface, I should like to state that I am an ardent advocate of true conservatism in gynecology, and I read this paper with the hope that the facts presented will aid in defining the proper course to pursue in dealing with a large proportion of the cases of uterine fibromyomata. There is, even in this advanced and brilliant era of surgery, great diversity of opinion as to the proper method of dealing with such cases. This diversity extends all the way from the ultra conservative, who would place his whole dependence upon the use of drugs, electricity, or a combination of the two, to the ultra radical, who would perform hysterectomy in nearly every case.

It is not my intention to present a treatise upon the technique of operations upon the uterus, but to revert briefly to their early history as bearing upon my subject, which has been one of especial interest to me. The method by which most of human advancement has been made is that of slow and steady steps, one mind adding to another its mite of progress until finally the present development of a science would scarcely be recognized by the originator of the productive idea. It is only comparatively rarely that some master mind sheds a flood of light upon a subject, thereby marking the beginning of an era.

The operation of uterine myomectomy is no exception to this rule. Its evolution has been gradual, notwithstanding the fact that to A. Martin, of Berlin, is usually assigned the credit for having been the first to perform it, and of inaugurating whatever of progress it may represent. Beginning with Lizar's case,[1] in 1825, the abdomen was opened fourteen times for supposed ovarian tumors; but as the operators found themselves confronted by uterine fibroids, the abdominal wound was immediately closed.

The first to attempt extirpation of a subserous pedunculated tumor was Granville[2] in 1829. His patient died. Vaginal enucleation was done with success by Ammussat and Velpeau in 1840. Lane, of England, successfully removed a pedunculated tumor from the uterus by laparotomy, on February 15, 1844. W. L. Atlee[3] successfully removed a pedunculated fibroid, weighing over two pounds, on August 28, 1844. Koeberle improved the technique of the operation for removal of pedunculated subserous tumors by employing the metallic loop and ligature tightener, which did away with hemorrhage.

In 1866 Caternault published twenty cases of gastrostomy for the extirpation of pedicled tumors. Spiegelberg,[4] in 1874, removed from the uterus a fibrocystic tumor of the posterior wall which he had mistaken for an ovarian tumor. The patient died.

In 1878 Sir Spencer Wells[5] advocated moving the tumor together with a wedge-shaped piece of the uterus. He enucleated an interstitial fibroid by the abdominal route, but the patient died of hemorrhage and shock four hours later.

This now brings us to an important point in the development of the operation, a contribution so important and of such interest that I present the following abstract of it:

Burckhardt reports a case as follows: On May 11, 1880, an unmarried woman, aged thirty-five, came to Martin's clinic on account of profuse menstruation. During the past year the metrorrhagia had been accompanied by colicky pains. About January, 1880, she began to suffer from anorexia, vertigo, anasarca of the legs, and rapid loss of strength. Upon examination at the clinic, she was seen to be highly anæmic, and the presence of a uterine tumor was recognized. The diagnosis was made of fibromyoma of the uterus, and an operation was demanded because of the excessive hemorrhage. The choice lay between vaginal and abdominal ablation of the tumor. To decide this point it became necessary to locate exactly its site. The essential and interesting features of the case were as follows: The cervix was first dilated with Barnes' bags and the tumor palpated with the finger in the uterus. It was located in the posterior wall. Because the patient did not well tolerate this vaginal interference it was decided to remove it by the abdominal route. The uterus was drawn forth by means of hands and forceps, and a rubber tube was tied about it, passing beneath the uplifted tubes and ovaries. The fundus and anterior wall were laid open, and the tumor projecting forward from the posterior wall was attacked from the front by splitting the mucous membrane of the posterior wall of the uterus. A piece of mucous membrane as large as the hand was removed with the tumor. The bed of the fibroma was obliterated by four deep sutures, and the mucous membrane united. The original incision in the fundus and anterior wall was then closed with superficial and deep sutures. The ovaries were found to be enlarged and cystic, and were extirpated. The operation required one hour and a half, and was done under carbolic spray. The patient was placed in bed with an ice-bag on the abdomen, and collapsed after coming out of narcosis. She ultimately recovered, after having an extensive abscess of the abdominal wall.

To this successful case of Martin and its accurate description and publication by Burckhardt we are indebted for the popularization of an operation which has since become one of the well-recognized surgical procedures, and which has, I believe, a most brilliant future. Its essential details have not been improved, but to them has been added modern technique. It is not easy for a surgeon of to-day to realize the difficulties under which one labored at that time, but the following quotation from Emmet's Gynecology[7] will serve to illustrate this: "Under certain circumstances it may be good practice to open the abdominal cavity for the purpose of removing pedunculated fibrous growths from the uterus, particularly now that the introduction of the antiseptic method has so greatly reduced the risk of such surgical proceedures." Again: "As soon as I had been able to satisfy myself of the existence of a sufficient length of pedicle I would not hesitate to perform the operation, if the pressure of the tumor caused great irritation." Again: "I have removed the whole or portions of the uterus in five instances and notwithstanding the greatest care to insure a favorable result all the patients died, sooner or later, from blood poisoning engendered about the stump." After quoting the statistics of hysterectomies for fibroid in the hands of seventeen of the world's greatest experts in the operation, which gave the following aggregate

*Read at a meeting of the Medical Society of the County of New York, May 27, 1901.

results. Number of operations, 359; number of recoveries, 227; number of deaths, 132; death-rate, forty-seven per cent. He goes on to state: "The general operator can in no wise approximate to these results."

The above quotations from the work of one of the greatest gynecologists of the time are of great interest as showing, in the first place, the crude state of myomectomy and hysterectomy at such a comparatively recent date as 1884, and, in the second place, the remarkable reduction of death-rate since that time.

Let us hear what a gynecologist had to say of prognosis in these cases in 1898: "With increasing experience in performing myomectomies, after eliminating the possibility of any grave extra-pelvic complications, and assuring himself that there is no extensive pelvic inflammation, the skilful operator will be able to assure all young patients with myomatous uteri which do not rise above the umbilicus that he will, in all human probability, be able to extirpate the tumors and leave the uterus, ovaries, and oviducts." What a vast contrast is there between the gloomy outlook for a woman affected by a fibromyoma in 1884 and the roseate prospect of 1898, and yet this change of views has not been due to the discovery of any one man, but the accumulated knowledge and experience of the many. The latter views are upheld by the present experience of Dr. Emmet.

The loss of the ovaries and uterus when occurring to a young married woman who has never borne children is a tragedy in her life. The value of the ovaries on account of a secretion peculiar to them is now well recognized, and systematic and to a certain extent successful attempts have been made[9] even to transplant healthy ovarian tissue to women who have been deprived of them by operation. The preservation of the uterus and its adnexa not only maintains the integrity of the pelvic structures and normal functions, but also offers a fair prospect of childbearing, as the following cases demonstrate:

Martin[10] says that most operable myomata must be attacked by laparotomy. This refers not only to pedunculated forms, but to the enucleation of intraparietal forms. The first operation of laparotomy ever performed for this class of tumors was done by the author and reported by Buckhardt in 1880. (This statement I have shown to be erroneous. The credit belongs to Spencer Wells.)

The following is a report of Martin's case: The woman had already borne four children. She developed symptoms of hemorrhage and endometritis, due to the presence of a myoma, and underwent operation May 3, 1889. The enucleation was performed without difficulty, and convalescence was uneventful. In January, 1890, the menses ceased, and pregnancy became apparent, its evolution being accompanied by moderate complications. In April, the patient had a fall, and an abundant hemorrhage set in. A physician summoned in haste believed the chance for survival had gone by, and so attempted to remove the embryo, but was successful only after several days. Martin concluded from the woman's statements that the ovum could have been retained and regrets that the case could not have been under proper control, because of the peculiar interest attached to it.

In regard to other cases, Hegar gave Martin the details of one of his own, never published, in which the patient, after a myomectomy, bore a living but poorly nourished child. Martin concludes by recommending the conservative operation. Especially in young women we should only remove the corpus uteri *with* the myoma when it appears impossible to retain those parts which perform its function.

Krönlein reports the following case in a paper entitled "Remarks on the Advantages of Conservative Procedures in Myomectomy":[11]

The patient was twenty-six years old, engaged and about to be married. The abdomen was seen to enlarge with the coincidence of backache. The menses were normal. Examination showed a tumor so incorporated with the uterus that the mass resembled that of a uterus at the sixth month of pregnancy. A uterine sound would not pass. A diagnosis was made of rapidly growing myoma, subserous and starting from the fundus. It seemed unwise to subject this young woman, healthy, and about to wed, to an operation, especially if sterility must result therefrom. The patient and her friends requested that if possible the ability to conceive should be left intact. On July 1, 1888, Krönlein performed laparo-myomectomy. The tumor was seated upon the fundus by a broad base, passing without any apparent line of demarcation into the uterus itself. The uterus and tumor with appendages were tilted forward, and Olshausen's rubber tube was applied. Schroeder's method of forming a deep wedge-shaped or conical cavity was adopted, with resulting excision of the tumor. It was at first believed that the cavity of the uterus had been exposed to a minute extent, but this opening was found to be a lymph-space. The two sides of the wedge were duly smoothed and coaptated by three planes of sutures, with a special peritoneal suture. As some oozing followed the removal of the rubber tube, other sutures were deeply placed for hæmostasis. The uterus was left in its normal shape, but was a trifle larger than normal. The operation, which lasted one and three-quarters hours, was a complete success. The tumor weighed nearly eight pounds (3½ kilo.). The convalescence was uneventful, and the patient was discharged in perfect condition August 1, 1888. On November 15, 1888, she married. The menses were regular, just as before operation, and the last period occurred on March 14, 1889. Confinement was expected December 22, 1889, but was a little premature (December 9th). The accoucheur, hastily summoned, found labor well under way. On account of poor action of the expulsive forces, the labor was terminated with forceps. The puerperium was normal. The child was a healthy girl. A year and a half after the operation everything was as could be wished, although in February, 1890, patient had one sharp attack of metrorrhagia. There was a good laparotomy scar. Krönlein closes by a strong plea for conservative work, for leaving the ovaries, etc.

Ascher[12] reports two series of cases, one of enucleations, the other of hysterectomies. In the fourth case of the first series the patient is mentioned as having become pregnant after the operation. The history is subsequently given in full: The patient, aged twenty-two, had her first delivery in July, 1884, by forceps. There was a normal puerperium. She did not nurse the child. The first menses occurred seven weeks later, at the end of August, but the woman did not menstruate again until the middle of October. On November 20, there began persistent loss of blood, constant pain over sacrum, and pressure upon the rectum. The bleeding was more profuse at the regular time for menstruation, and was lumpy, but no decidual fragments were present. She had always been regular as a girl, the menses having been profuse and painful. The woman was examined under narcosis on January 20, 1885. The uterus was strongly anteflected; it was nine and one-half cm. long, the cavity was moderately wide, and the mucosa bled readily. Behind the uterus could be felt a very hard mass about the size of the fist, slightly movable upon

the uterus, which was continuous—save for an intervening fold—with a second mass which filled the entire right side of the lesser pelvis and iliac fossa. The tumors were constantly increasing in size, and were becoming more painful.

An operation was performed on January 26, 1885. A diagnosis had been made of subserous, retrouterine myoma plus some interligamentous formation, either hæmatoma or ovarian tumor. After laparotomy the myoma was found as per diagnosis. It had a broad base, and was readily enucleated, its bed being closed by suture. The larger mass was an old hæmatocele in the broad ligament, perhaps the remains of an extra-uterine pregnancy. The sac was emptied, closed by suture, and drained by the vagina. Convalescence was uneventful. Ascher simply states that this woman became pregnant in 1888, and had a normal labor. He makes no comment upon this fact, perhaps the first on record of its kind.

Werder reports a case of myomectomy with extraperitoneal treatment of the pedicle, followed by pregnancy and complicated by hemorrhages through the abdominal cicatrix.[13]

The patient, aged twenty-nine, had been married for a year, but was sterile; she had a large peritoneal fibroid of the uterus, with short, thick pedicle, which was treated extraperitoneally by elastic ligature. Eight or nine weeks later she became pregnant, while there was still a small sinus at the lower angle of the wound. The pregnancy was uneventful until the end of the fourth month, when hemorrhages took place through the fistula, which had meanwhile become larger from expansion of the abdomen. These hemorrhages recurred at regular intervals and caused considerable anæmia. Labor set in three weeks ahead of time, lasted twenty-four hours, and was terminated by forceps. The child was poorly developed. The placenta was adherent immediately beneath the fistula and required manual separation. As some of the uterine wall was gone at this point, the placenta actually adhered to the abdominal parietes, and was detached manually. The patient made a good recovery and left the hospital with fistula closed. The menses returned with hemorrhage through the fistula.

In an article entitled, "On the Question of Conservative Operations for Myoma and the Subsequent Functions of the Uterus," Muller[14] reports the following case: The patient was twenty-five years old, and had a large interstitial myoma of the anterior and left aspects of the uterus, which appeared soon after her first pregnancy. Hemorrhage, fever, and pain indicated beginning necrosis. The patient would not consent to be made sterile. Laparotomy was performed, the anterior uterine wall was split (under hæmostasis), and a tumor as large as three adult fists was enucleated, in part by the blunt method. The uterine cavity was opened to about the same extent as in Cæsarean section. As part of the anterior wall was suspiciously soft it was resected to the extent of half the size of the palm of the hand. The large uterine wound was then closed by catgut. The parietal peritoneum was also stitched about the uterine wound, and the cavity of the abdomen was drained with iodoform gauze. Convalescence was uneventful, and one year later the woman conceived; pregnancy advanced without any disturbances, and at the beginning of the tenth month a child was born, unfortunately dead, death having been due to foot presentation and suffocation by the umbilical cord.

Woyer reports a case of pregnancy and childbirth after abdominal myomectomy.[15]

The patient was thirty-four years of age. The menses began at fourteen, and were normal, lasting from three to six days. In 1882, she first noticed the presence of an abdominal tumor, which rapidly enlarged and was extirpated by the late Professor Bandl. The author had the opportunity of studying the record of the case made at the time. The tumor weighed over fifteen pounds and the length of operation was two and a half hours. The pedicle was cared for by the extraperitoneal method, and the elastic ligature was employed. The patient left hospital, having had weeks of after-treatment. The menses reappeared and were of the original type. A small, fistulous opening remained, and during the menses some drops of blood were discharged from it. In March, 1896, no menstruation having appeared for eight weeks, an abortion is said to have occurred. For the next six weeks blood escaped from the uterine fistula. In August, 1896, the periods, which had become regular and natural, again ceased. The abdomen began to enlarge, and fœtal movements were felt in January, 1897. Up to this time the patient had felt entirely well. On January 11th-12th, there was sudden and profuse hemorrhage from the fistula which caused her to seek hospital treatment.

The laparotomy scar was seen to extend to within two fingers' breadth of the navel, and at its upper end the fistula was seen. The uterus was evidently pregnant, the child being in the first transverse position. The fœtal heart sounds could be heard. Under simple rest in bed, the woman became perfectly free from symptoms and left the hospital January 27. She returned March 6, with slight hemorrhage from the fistula, which had also occurred on several prior occasions. She had become somewhat anæmic. The sound, passed into the fistula, brought forth a serous fluid tinged with blood. She was again placed in bed, and a compress was applied, and once more the symptoms subsided. There was one sharp attack of hemorrhage following a coughing spell. On April 6th there was a sudden escape through the fistula of a large amount of colorless fluid, in which were seen some necrotic shreds. Labor set in the night of April 7th to 8th. The fistula had now become patent to the finger, and when the latter was withdrawn the membranes could be seen to bulge at the orifice of the fistula. The pains were very strong and labor took place spontaneously, the child having assumed the natural position. The uterus contracted well after delivery, but the adhesions kept the fundus high up in the abdomen. The placenta came away naturally, and there was no postpartum hemorrhage. The child was still-born. Autopsy showed nothing but atelectasis and anæmia. The lochial secretion also came away through the fistula, and by May 23d the discharge had completely ceased, the woman being perfectly well.

Engström,[16] in an article on "Abdominal Enucleation of Myomata of the Corpus Uteri—Martin's Myomectomy," reports one hundred cases in detail. Under the head of pregnancy, he states that in isolated cases this may result; Martin had seen two such instances in one hundred and thirteen cases of operation—one ended in abortion, while the other went on to term.

Engström's four personal cases were as follows:

Case I. (No. 37).—Aged thirty-nine. The operation was performed April 25, 1893. A myoma, the size of a child's head, telangiectatic, and partly decomposed, was removed. It was enucleated from the posterior wall. The woman had been married seven years before the operation without having conceived, conception following upon the operation. The menses first ceased at the end of September, 1894. She contracted some kind of a fever and aborted February 20, 1895, being left with purulent metritis, etc. She again became pregnant and again aborted in the third month, at the end of May, 1896.

Case II. (No. 39).—The patient was married one

year before the operation, but never conceived. She became pregnant one year after the operation, which was severe. The uterus was adherent behind to the pelvis. Ten intramural myomata, from a hazelnut to a hen's egg in size, were enucleated, and one pedunculated growth the size of a duck's egg was ablated. The woman aborted in the fourth month after a long, rough ride.

CASE III. (No. 50).—In this case a myoma the size of a hen's egg was enucleated from the anterior wall of the corpus uteri. The woman was then single. As soon as opportunity for conception occurred, pregnancy resulted. All went well and a living child was born without artificial aid.

CASE IV. (No. 87).—The patient had been married twenty years before the operation and had aborted three times at the second or third month. The last abortion occurred six months before the operation. During the operation several loops of intestine had to be detached from the left ovary and fundus uteri. The left ovary was extirpated, and a myoma as large, as an English walnut was enucleated from the depths of the anterior wall. Eight months later the patient conceived, and at the time of the report was now three months pregnant.

As only twenty-two of these hundred women were both married and in the child-bearing period, the proportion of subsequent pregnancies was high—one case in somewhat less than six chances.

Amann stated, in a discussion on myomectomy before the German Gynecological Society, May, 1899,[15] that he once enucleated a myoma as large as a child's head from the posterior wall of the uterus, and the woman afterwards passed through a normal gestation and delivery.

Johnston[16] says that he has performed thirty-two myomectomies. In one case he removed seven tumors from one patient on account of sterility. She soon became pregnant, aborted at third month, again became pregnant, and went on to term.

On January 28, 1899, I saw Mrs. G. (referred to me by Dr. E. A. Davis, of New York), aged thirty-three years; she had been married two years, but had never been pregnant. Her first menstrual period occurred when she was fourteen years old, and she had since been regular every twenty-eight days; the duration of the flow was from four to five days. Menstruation was at first painful, and continued so until recent years, when it became free from pain, with the exception of the two occasions, the last of which caused her to seek the aid of a specialist. These periods were accompanied by severe and lancinating pains which led her to believe she had some uterine disease. The bowels were constipated, the appetite was fair, and sleep was not disturbed.

Bimanual examination showed the uterus to be converted into a mass of fibromyomata reaching nearly to the umbilicus. Myomectomy was advised.

On March 16, 1899, under ether narcosis a median abdominal incision five inches long was made. The uterus was drawn out of the incision on to the abdomen, and an elastic ligature was passed about its lower segment as low down in the pelvis as possible. After this had been secured the enucleation of the fibroids was begun. Sixteen tumors were removed through nine incisions. They varied in size from that of a hen's egg to that of a pea.

Each incision was carefully closed with No. 2 chromicized catgut (a suture absorbed in twenty-three days). Some of the deeper openings were closed from the bottom with layers of the same material placed in continuous suture, the remaining sutures, which passed through the muscular layer, being interrupted and at distances of about a quarter of an inch apart. Toward the end of the operation several very small tumors were discovered deep down in the tissues of the uterus by taking the now almost normally shaped organ between the thumb and fingers and feeling for them. They gave much the same sensation as that of a bullet buried in soft tissue which could be grasped between the fingers and thumb. These were cut down upon and dragged from their beds by means of a tenaculum, and deep catgut sutures were used to obliterate the cavities and close the wounds made in removing them. After all the tumors had been removed and the uterine wounds had been closed the elastic ligature was removed. There had been no loss of blood up to this point, but now there was considerable oozing. I applied compresses wrung out of very hot water repeatedly, but some points continued to bleed so freely that I deemed it wise to place some additional superficial sutures. In about ten minutes all bleeding had ceased, and the abdominal wound was closed with through and through silk-worm gut sutures. There had been no perceptible shock, and the patient was put to bed in good condition. No stimulation was necessary, and she made a perfectly uneventful recovery.

In August, 1900, Mrs. G. consulted me on account of symptoms of pregnancy. Examination revealed the fact that she was pregnant, the uterus being uniformly enlarged and showing no evidence of myomatous growth. On January 8, 1901, I was called to attend her in confinement. She was in labor for twelve hours and had rather an easy delivery, with vertex presentation and no complication save that of a slight laceration of the perineum, which was repaired at once with silver wire sutures. The baby was a boy and weighed seven and three-quarters pounds.

At this date both mother and child are in excellent health; and the uterus has undergone normal involution, and there is no sign of any tumor.

In Martin's case, there was no thought given to future pregnancies. His chief reason for doing myomectomy rather than hysterectomy seems to have been that he considered the former operation less dangerous than the latter. He removed the ovaries because they appeared to be enlarged. It is unfortunate that he did so, as otherwise his patient might have been absolutely cured, physiologically as well as symptomatically. It has been my observation that nearly all ovaries are enlarged in cases in which the myomata have reached any considerable size, the process being only a part of the general hyperplasia due to the increased blood supply of the uterus and its adnexa. It may, therefore, be reasonably expected to disappear with the resumption of normal conditions brought about by the removal of the tumor. This simple enlargement of the ovaries does not constitute sufficient ground for their removal, and they should in every case be left. Let us then not remove ovaries in partial or even complete hysterectomies for fibromyoma, unless there exists some powerful reason for doing so.

Unfortunately for the obstetrical side of these cases, no careful records were kept, but the following points are of interest. There are fourteen cases reported with eighteen pregnancies, three patients having been twice pregnant. Of the three patients who were twice pregnant there were two healthy children born. There were in all nine healthy children born at the normal term. Two children went to the normal period of gestation and were born dead. There were six abortions, most of them occurring at from three to four months. One pregnancy was still going on when reported at the third month. It is exceedingly interesting to note that although all these uteri had extensive scars from having had tumors enucleated

from them, in but two of the cases was it necessary to use forceps. All had normal presentations.

In the author's case, in which nine incisions had been made into the uterine tissue, the labor lasted twelve hours, and the expulsive force was ample, the only complication having been a lacerated perineum. In two cases gestation was complicated by a flow of blood or amniotic fluid from utero-abdominal fistulæ, which remained at the side of operation, but healthy children were born notwithstanding this complication. There were no abnormal positions and no puerperal complications.

71 WEST FORTY-NINTH STREET.

THE SUMMIT FISSURE.

OVERSPHERE AND UNDERSPHERE.

BY WALLACE WOOD, M.D.,
NEW YORK.

ACROSS the face of every cerebral hemisphere runs a zone of light and a zone of sound. Between the two there is a great gulf fixed, the lateral fissure. In the bovine brain this is clear. Now the eye gyrus and ear gyrus are at the summit of the sphere, hence this cut between them is the summit fissure.

There is an anterior sound and a posterior sound, and an anterior light and a posterior light, so the fissure is both anterior and posterior. In the human brain, between the sound and the light of the anterior, this fissure is called the second frontal, and between the sound and the light of the posterior, it appears as the end of the first temporal. In the ox this fissure is immense.

Brains fall into two grand divisions, the militant and the civil; and to the civil or industrial division belong *Bos taurus* and *homo*. Among all the cerebral hemispheres we may learn most from that of the ox. Lead forward the horned ruminant, therefore; let his simplicity explain our complexity.

A vertical line divides a body into fore and after; a horizontal line divides it into over and under or superior and inferior. The vertical line in the ox brain is the fissure of Sylvius; the horizontal line is the great lateral fissure, a wide and deep chasm, separating the temporal from the occipital lobe, that is, separating the mental eye from the mental ear, or the auditory area from the visual area.

In human brains this fissure is the first temporal, and, tracing backward, it is seen to separate the auditory and visual areas, projecting also into the auditory area. Between seeing and hearing in the bovine cerebrum there is a great gulf fixed. In order to become aware of this one must find it and fall into it. This the student will assuredly do if he dissect a bovine cerebrum. The hemisphere in hand seems veritably to be of two pieces, an upper and a lower. So deep and ghastly is this gaping cut, you can lay the pencil or the finger into it easily. Next to the fossa of Sylvius, it is the most prominent feature.

What is this great furrow; what is its significance?

What is above it? The eye gyrus. What is below it? The ear gyrus. In all the gyrencephala it separates the temporal from the occipital lobe, the mental eye or house of vision from the mental ear, the house of audition. The eye gyrus and the ear gyrus are the zones that stretch along the summit of the sphere; therefore, this extraordinary gulf between the two cuts the summit of the sphere.

Three gyri sweep around it on the one side and three upon the other. Much as the fissure of Sylvius divides the sphere vertically into an anterior and a

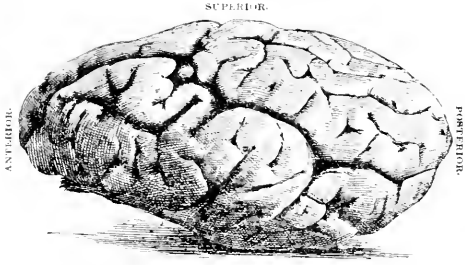

Fig. 1. Brain of *Bos taurus*, showing the great lateral fissure (summit fissure). Above this is the eye lobe; below it the ear lobe.

posterior, this horizontal fissure divides the sphere horizontally into a superior and an inferior. These two fissures then cut the sphere into four quarters; they are, or appear to be, in the bovine brain the *cardinal* fissures. Below this great cut are three gyri, the hippocampal, the Sylvian, and the ectosylvian. These three gyri culminate each in a head or lobule, the hippocampal lobule, the sphenoidal pole, and the temporal eminence. These are the centers of smell, taste, and hearing; these three lobules are to be regarded as the psychical heads of the olfactory nerve, the glossopharyngeal nerve, and the auditory nerve. Taste, smell, and hearing are inferior to the fissure; they belong to the under or lower half of the cerebrum. Above the fissure lie three other gyri, the fornicatus, the marginal, and the lateral. These three superior gyri are connected first with the eyes and next with the vast tract of the sensitive nerves and the motor nerves. By means of these three gyri the animal is a visile and a motile, and endowed with high sensibility, tactile and motile.

Thus, the superior half of the cerebrum appears to dominate the eyes, the head, the neck, the shoulder, hand, the vertebral column, the legs, and the tail; in other words, the dorsal half of the body, while the inferior portion connects with nose and ears, mouth and tongue. The brain by this fissure, then, is divided into a dorsum and a ventrum or an overcorps and an undercorps. To the superior half or hemisphere, the cerebral dorsum, the overcorps, belong the vertebral column, with its seven parts, the head, neck, trunk, and tail, the eyes, the arms, and the pelvic girdle; for these are connected with the fornicate, marginal, and lateral convolutions.

On the other hand, the interior half of the cerebrum, that is, the inferior three convolutions—hippocampal, Sylvian, and ectosylvian gyri—are as certainly connected with the lips, the jaws, the tongue, the larynx, the pharynx, the viscera, and the genitalia, probably also the muscles and skin of the ventral aspect of the animal. Thus, in the three inferior gyri, the cerebral ventrum is the arborescence of olfactory, maxillary, glossopharyngeal, auditory, laryngeal, palatine, gustatory, pharyngeal, pneumogastric, intercostal, phrenic, cardiac, sympathetic, splanchnic, pudic, and pudendal nerves. It constitutes the intimate or intensive sphere of sensibility. Audition lies in this sphere.

An ox, a sheep, a deer, is a vertebrate by his spine and limbs, his vertebrate system, but an invertebrate by his ribs, ears, and jaws, which belong to his invertebrate or branchial system.* The branchial system is proximate (cardiac, pulmonary, phrenic, respiratory), while the vertebral system seems built around and upon it, hence is extended or distal.

What are the physiological functions that belong to the branchial or more intimate or under-inner half of the body? They are digestion, circulation, respiration, ingestion, egestion, reproduction, smell, taste, mastication, audition, and phonation.

The brain of the ox teaches us that audition and phonation are more intimate than vision and locomotion, belonging in fact to the intimate and inferior sphere. This is extraordinary. What connection or likeness can be found between audition and the intestinal tract? Let us see. A little thought will show us that every part of this lower, inner, or branchial system is grooved or tubular. The intestines are tubes, so are veins, arteries, so are the respiratory tracts and the excretory and secretory. Taste and smell lie in grooves. Audition and phonation grow out of the system. Of all this interior tubular tree, they are the spiritual flowers.

Intestines are material tubes, while vocal and auditory apparatus are spiritual tubes, that is, carrying only airs, waves, and tremors; nevertheless essentially tubular.

The superior or distal sphere of the body offers a contrast. The vertebral system is the base. The surrounding and superior sphere lies not in tubes, but in stems, plaques, and surfaces; a head, a neck, a tail, a leg, an arm, these are solid masses. Each one of these is a tactile-motor mechanism. The eye belongs with these; it is a flower of the cutaneous and muscular trunk, a flower of the tactile-motor sensibility, a flower of the vertebral stalk, of which arms and legs are branches. Ears and voice are flowers of the tubular tree; eyes and hands are flowers of the solid stalk, the vertebral tree.

Morphologically, according to Owen and Huxley, the body of a vertebrate consists of two tubes or hollows, the inferior intimate blood tube and the extra nervous tube—that is, a dorsal hollow and a ventral hollow. Morphologically, again, the body is built upon two axes, the intestinal or ventral axis and the dorsal or spinal axis; or, again, into a vertebrate and invertebrate or branchial half; or, again, it is made up of somatopleure and splanchnopleure; or, again, divided into vegetate and animate as regards function.

The above idea presented, as regards the body, in five different ways, forces itself strongly upon us as we find our ox brain falling so plainly into two halves, and when localization shows that of these two halves the over half is full of eyes, legs, and arms and heads and shoulders, *i. e.*, eye, leg, arm, hand, and shoulder centers, and the lower half full of ears, lips, tongues, nostrils, and jaws and vocal cords, that is, lip, tongue nostril, and maxillary centers, we seem to see a natural, longitudinal division in the brain-spheres similar to those found in the body-sphere.

Ears and viscera go together; eyes and limbs go together. Trace the oversphere. The significance of the eyes and vertebral column in fishes appears to be this—better locomotion—that is, better as compared to the invertebrata. With the reptilia, the added pair of girdles adapt this grander locomotion to land progression; and with birds the two girdles and the neck adapt the creature to progress on both air and land, and to a better prehension by the long neck. In the horse or deer these extensive powers, vision, locomotion, prehension, are well displayed, and the point of interest here is that the spirit of these powers resides in the superior half of the cerebrum, the half comprising the three arches above the horizontal fissure.

Eyes and limbs go together; ears and viscera go together. Trace the branchial or inferior and more intimate body sphere, the undersphere. In fishes it appears like a sack with a wide mouth; it is progressively differentiated and integrated as we pass to reptiles, birds, mammals. Intimate prehension, better mastication, better forms of heart and lungs, better ingestion, egestion, and reproduction are found as we ascend, but the curious part is that audition and phonation belong to this more intimate sphere of breath and blood. Those hollow organs, ears and larynx, are engrafted upon it just as are the grooves of nose and tongue; once more we seem to see them as the flowers of the tubular tree. They are close to the throat, heart, breath, and life-blood; they are filled with the language of the heart and the spirit.

Touch, movement, and sight are exterior and locomotor may be familiar, but not intimate; taste and smell are intimate. Smell, taste, hearing, and voice and the love passion and the biting of wrath or hate, these lie literally nearest the heart, the heart's blood and the milk of the breast, the blood of life and the breath of life and the sacred tree of life. Taste and smell are intimate senses, hearing and sight are distant senses, touching and handling are familiar senses.

If, however, we group three against three, ears, nose, and tongue go together as intensities or belonging to the under-inner sphere, while eyes, hands, and legs go together as extensions or belonging to the over-outer sphere. We may apply the measure to the body of a lion. The rampant legs, the striking paws, the flashing eye, and lashing tail, all are parts of the overcorps, and are members and mechanisms operated by the oversphere of the cerebrum, that is, the extension soul; while the nose and ears and the blood-red mouth and flame-like tongue, the reverberating roar of the expiring breath, and the ardent heart of generation are intense and most intimate parts and forces, and are of the undersphere. The mouth, the voice, the audition of a feline are more intimate powers; the eye and griffs are extension powers.

If the measure will apply to the lion, so also will it apply as well to the lamb. Seeing and going and grazing are extensions, while smelling and tasting and eating, hearing and bleating, are intense. The family relations are intense and intimate. Seeing and going and grazing are acts performed through connections of the overcorps and by the overanimus, while scenting, listening, bleating, eating, begetting, are acts performed through connections of the underbody and by the intimate animus.

Which sphere is greatest? Nothing can be more wonderful than touch, sight, and locomotion. These are the mechanical and etherial powers. Nothing can be more wonderful, except the anemos (the pneuma, the psyche) and the word, the spiritual powers, hearing and speaking and the power of reproducing.

Which sphere is greatest? In the closer, the heart and breath sphere are hearing and speaking, surely the

* See the osteology in Wiedersheim and Gegenbaur.

most spiritual and most intellectual powers and faculties. Here also are smell and taste, the fountains of sweetness and purity; here also eating and loving, which are the springs of love and hate. Touch, sight, and locomotion, are they greater than these? The eye, with the hands and feet, might hold a contention against the ear with the nose and the mouth, each side claiming superiority.

Once more we note, we must note, this curious fact that hearing and speaking belong to the more intimate vital sphere, belong with the acts and pathies of loving and biting, of smelling, tasting, sucking, licking, eating, hungering, struggling, and that, on the other hand, seeing and direction do not belong to this sphere, but to the wider and higher sphere of the legs and arms and vertebral column, the backbone of us.

Several deductions follow. By the superior arches of the brain, an animal is visile and motile, while by the inferior arches of the brain he is audile and olfactile. Primates are strongest in the one and bovines in the other. Primates (man) are visile-motile or souls of the eye and hand; lower mammalia are olfactile-audile, or, as it were, souls of the nose and ear.

From the metaphysical point of view, we may say that in the superior hemisphere reside force and form, while the inferior hemisphere is perhaps more the abode of plasm and spirit. These data may give us a rule to be applied to anthropological and ethical science. Whole races of men are olfactile-audile, souls rather of the nose and ear, more or less intimate and spiritual, more or less chemical and spiritual, more or less intense—as, for instance, the Hebrews.

Other races are visile-motile souls, more or less mechanical and etherial, souls of the eye and hand, such as the ancient Hellenes—extension souls. Hebraism is intense, Hellenism is extended. So, also, even as Hebrews are olfactile-audile souls and Hellenes are visile-motile souls, so the romantic spirit may be regarded as in a way olfactile-audile, that is, material-spiritual, while the classic spirit is motile-visile, that is, mechanical-etherial.

Two typical and terrible forces, the generative and the destructive, or love and wrath, lie in this inferior sphere. The two strongest of the gods, Love and War, rage through it in storms and calms. On the other hand, two other powers, Ambition and Pride, sit Hera-like and Jupiter-like enthroned above; they belong to the superior sphere.

The fine arts lend themselves to this division. Music, eloquence, rhapsody, rise in the under, inner, inferior, more intense, more intimate sphere. Architecture, sculpture, and painting and letters rise from the upper, the superior, the extension sphere. Cultus and culture will also fall into line. The art of dining, the arts of perfumery, and cleanliness (cleanliness is next to godliness), the most wonderful of all arts, marriage and parentage, belong to the under, the more intense, more intimate sphere. The place of the sacred hearth, the home and mother, are also here.

Other powers, wonder and fear, born of the eye sensibility and skin sensibility, these with supernal or reflected attachment give rise in the oversphere to the religious sentiment.

The art of living and thriving shows two spheres. Economy and sagacity, with their arts and ways, appear to belong to the undersphere, the under-inner sphere, while the mighty arts of Building and Engineering are extensions of the oversphere.

Three grand passions sleep and awaken in the inferior sphere. They are the love passion, the hunger passion, the anger passion. Three grand passions sleep and awaken in the superior sphere. They are the passion for rank, the passion for power, and the passion of pursuit.

NOTES ON MALARIAL FEVERS IN CENTRAL AMERICA.

By J. HOBART EGBERT, A.M., M.D., Ph.D.,
SAN JUANCITO, HONDURAS,
SURGEON TO THE NEW YORK AND HONDURAS ROSARIO MINING COMPANY.

THE question of the propagation of malarial fevers by mosquitos has been made the subject of much discussion, and it is evident that most observers have accepted the preconceived theory of the inoculation of the human organism with the plasmodium malariæ through the agency of these troublesome insects as a demonstrated fact. But there is another distributing agent, active in some parts of the world which should not be overlooked. Here in the mountains of Honduras, four thousand feet above sea-level, we are above the mosquito belt and, as that term is generally employed, above the fever belt as well; and yet malarial fevers—both quotidian and tertian types—are of common occurrence. From what do they arise? The climate, generally speaking, is salubrious, with an equable, medium temperature the year round; there is an abundance of good water, and from the very location of the pueblo, well up the steep side of a lofty mountain, excellent natural drainage is afforded. It is true there are people passing to and from the coast one hundred and twenty miles distant and other low districts, but these are not the only ones who suffer from the fever; neither is it limited to persons predisposed to its manifestation by previous attacks. We cannot admit a quality of contagion, as that word is properly used; and, as already stated, both geographical and topographical features show that it is not indigenous to the locality.

How then is it propagated? Whatever other methods there may be, one, at least, is patent to the writer and that is by inoculation—not by mosquitos, for they are practically unknown here—but by fleas. The fleas here, as in other parts of the country, are constantly with us, and scarcely a day passes—except it be in the height of the rainy season—but what a person who is in contact with the natives, or who does not keep his own surroundings scrupulously free from dust and other debris, feels a demand to move anywhere from one to a dozen fleas from the surface of some part of his anatomy. They greatly molest the uninitiated Gringo; but, although they most certainly bite, they do not greatly annoy the native and the acclimated.

Circumstantial evidence is sufficiently abundant to convince the careful observer that the fleas transport the malaria. The writer's attention was first seriously directed to this subject by the prevalence of malarial fevers among the soldiers in the local cuartel. Out of the twenty or so native soldiers on duty here, there were usually from one to three down with fever. At times the occurrence of fever was easily accounted for in an individual, as in a new recruit who had recently arrived from a generally malarious district, but its almost constant occurrence there and apparent lack of selection were not easily explained. At length, the fleas, which never failed, at least of attempt, to make an impression upon the writer whenever he visited the cuartel, seriously engaged his attention. The more liberal use of the broom and of water, and also the thorough daily cleansing of the berths of the soldiers and the dusting of corners and crevices with powdered borax, were enjoined, and, although general cleanliness among persons thus quartered and who almost habitually sleep in their clothes (which, by the way, is entirely contrary to the custom of the ordinary native, who covers his or her naked body with a

blanket—previously shaken—and thus escapes much annoyance by fleas) was not to be expected, and although, *por fuerza*, a high degree of those conditions necessary for the abolition of the fleas was practically impossible, nevertheless, after accomplishing what was possible in this direction, the amount of fever among the soldiers decidedly decreased.

It is a matter of regret that there is not at hand a suitable microscope for determining whether or not the plasmodium malariæ can be demonstrated in the blood drawn by the fleas from patients suffering from malarial fever—this, however, will receive our attention at a later date.

Malarial fevers in tropical America present certain features of special interest to the clinician. To him who still retains a fair remembrance of the anatomical discourses of collegiate days, the part played in the pathology of this disease by that portion of the circulation comprehended by the vessels of the cœliac axis and the organs with which they are so intimately related, cannot escape observation. The liver, the spleen, and the stomach are all involved: the latter, apparently, quite passively, the liver quite actively, and the spleen energetically. The writer has frequently submitted to careful physical examination victims of various attacks of tropical malaria—both during an attack of the fever and after varying periods of time have elapsed since an attack. During an attack the gastric and hepatic disturbances are usually quite severe, but it is the splenic involvement which is often a particular cause of trouble after the regular routine fever and chills have passed. So common is this disturbance of the spleen that many natives who present themselves for treatment of digestive disturbances, and particularly of those accompanied by pain and swelling of the abdomen, frequently remark: "*Quién sabe, si es inflamación del bazo que tengo*" ("I don't know if it is inflammation of the spleen that I have"), or they will make a positive, and sometimes correct, diagnosis, and say, "*Tengo el bazo inflamado*" ("My spleen is inflamed") and specially request remedies for the same.

Certain it is that "el bazo" is frequently inflamed and enlarged, even among children. The writer has frequently found it encroaching on the diaphragm above, extending laterally from the lumbar region behind to beyond the median line in front, and reaching down into the pelvis. At the same time there is occasionally encountered a greatly enlarged or congested liver, all together producing considerable protuberance of the abdomen, dyspnœa, digestive disturbances, great debility, etc. Under treatment, however, most cases generally do very well.

The general plan of treatment for these malarial fevers and their sequelæ, which I have found to yield the best results, is the administration of quinine and acetanilid in combination, together with calomel or saline laxatives, during the run of the fever; and quinine and mineral acids—or Fowler's solution—together with podophyllin, or similar hepatic stimulant, for the subsequent disturbances.

The "Fourth Disease."—By this designation J. J. Weaver refers to an eruptive disease having some of the characteristics of measles, some of scarlet fever, and some of German measles, perhaps resembling scarlet fever more than either of the others, yet apparently distinct from all three. The following are the points of distinction advanced by the author: The rash is indistinguishable in character from that of scarlet fever In all his cases, however, unlike scarlet fever, it appeared first on the face—generally round about the mouth. In the next place, even when the rash is extensive—for instance, all over the front and back of body and limbs—the temperature is not high—not above about 100° usually—and the pulse is not accelerated, as one would expect to find in scarlet fever. In fact, the "fourth disease" is to be distinguished, as far as his present experience goes, by the fact that, in spite of an extensive and well-marked scarlatinal rash there is little or no rise of temperature or pulse, the throat symptoms are slight or absent, there is little or no feeling of illness, and no loss of appetite (the patient eats, or wishes to eat, his food as usual). In addition to the above points of distinction, Dukes lays a good deal of stress—in distinguishing "fourth disease" from scarlet fever—on the tongue, which in scarlet fever peels on the fourth day, but in "fourth disease" does not. In all other respects "fourth disease" is very like German measles—the eruption is usually the first symptom in both diseases, the incubation period is from nine to twenty-one days, and the throat and eye symptoms are much the same. In none of the cases here recorded as "fourth disease" was there any sneezing, coryza, or cough. The enlargement of the lymphatic glands—particularly of the posterior cervical glands—which is said to be pretty general in German measles, does not appear to be so general in "fourth disease." In none of the cases recorded in this paper was any enlargement noticed, nor was there complaint of them by any of the patients. Opinions differ as to the existence of desquamation, the general consensus of opinion being that it does not occur.—*Dublin Journal of Medical Science.*

Home Treatment of Phthisis.—Guy Hinsdale considers home treatment to be usually a makeshift, adopted from necessity and rarely from choice. Persons who leave their homes for hospitals, sanatoriums, and even open resorts, will do more for themselves than they would at home, and conform more readily to the régime prescribed. City air is impure, full of dust, smoke, carbonic-acid gas, and pathogenic organisms; moreover, at home, in the winter, the transitions regarding relative humidity vary too greatly between indoors and outdoors. Under the open-air treatment, the patient has few, if any, of these transitions. In Colorado and New Mexico he has dry air all the time. The place where a person has contracted phthisis is usually not a good place for him to remain for treatment.—*Pennsylvania Medical Journal.*

The Pancreas in the Infective Diseases of Childhood.—Dante Pacchioni states that the pancreas undergoes degenerative or inflammatory changes in the infective diseases of childhood, the former being the more frequent and consisting in fatty degeneration of the cells of the acini This has been found in diphtheria and in tuberculosis. Increase in the interstitial connective tissue was found in a case of congenital syphilis. It must be borne in mind that cadaveric decomposition causes profound changes in the pancreatic cells. The clinical diagnosis of these alterations in the pancreas in infective diseases is not as yet possible. To them we may ascribe the transitory glycosuria and profound and rapid emaciation sometimes observed in cases of diphtheria or scarlet fever.—*Lo Sperimentale.*

A Case of Tropical Abscess of the Spleen with Sterile Pus.—E. Albert reports a case from Algeria. The affection, corresponding to hepatic abscess, is as yet little known; the author has been able to find only nine cases in the literature of tropical pathology. The conclusions reached from his case and from the others are that malaria plays a part in the etiology by predisposing the organ to disease; that there are some abscesses in which the pus is sterile, and that the pus, which usually opens into the abdomen, may, by means of peritoneal adhesions, find its way to the exterior, and take on the aspect of an abscess of the abdominal wall.—*Revue de Médecine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 17, 1901.

THE NATURE OF PARETIC DEMENTIA.

THERE is reason to believe that while syphilis is far and away the most common cause of paretic dementia, as it is likewise of tabes dorsalis, it is not the sole cause. It would seem, further, that it is not syphilis directly that is the responsible factor, but that the nervous disease occurs as the result of some secondary effect. This, it is likely, is of a toxic character, and it is an open question whether it is exerted upon the nervous elements directly or indirectly through the blood-vessels. Some interesting observations bearing upon this important subject are recorded in papers read at a recent meeting of the Medico-Chirurgical Society of Edinburgh by Dr. Lewis C. Bruce and Dr. W. Ford Robertson (*British Medical Journal*, June 29, 1901). The former expresses the opinion that the alimentary system is invariably affected throughout the whole course of the disease—obstinate constipation, biliousness, capricious appetite, gastric crises, and failure of digestive and assimilative power being common symptoms. From personal observation he is, further, in accord with the view that the temperature of general paralysis of the insane is characteristic, the peculiarity consisting in a recurring febrile attack every one or two weeks. This he regards as expressive of the resistive reaction of the body to some toxic influence, and as confirmatory of this belief he considers the hyperleucocytosis that he found always to accompany the elevation of temperature. Remission in the symptoms was observed in some cases complicated by acute infection, such as erysipelas, pneumonia, or carbuncle, and it was preceded by marked hyperleucocytosis. In other instances, such remission was associated with improvement in the powers of the alimentary system and also with leucocytosis. Under such circumstances, the blood-serum was capable of causing agglutination of bacillus coli in dilutions in which the blood, from patients in a progressive stage or from healthy persons, was inactive. Upon the basis of this experience, blood-serum from a patient in a remission was injected into a patient in the progressive stage, with the apparent result of ameliorating the symptoms. As the outcome of these observations, the conclusion is expressed that general paralysis is a disease due directly to poisoning by the toxins of bacteria whose point of attack is through the gastric and intestinal mucous membrane. This poisoning is probably of a mixed character, but the bacillus coli is apparently one of the noxious organisms. The result of treatment with serum taken from a case of general paralysis in a condition of remission and injected subcutaneously into an early progressive case points strongly to the fact that some form of serum-therapy is the proper treatment for this as yet incurable disease.

As the result of a histological study in fatal cases of general paralysis of the insane, Dr. Robertson concludes that the disease is dependent upon the occurrence of a chronic toxæmia of gastro-intestinal origin, the toxins being mainly bacterial, and formed in consequence of a partial breakdown of those forces by which the harmful development of the micro-organisms that constitute the ordinary flora of the alimentary tract is normally prevented. The toxins are absorbed and tend especially to produce proliferative and degenerative changes in the vessels of the central nervous system. These vascular changes tend to set in earliest in those parts of the brain that are relatively best supplied with blood because their walls are brought in contact with the largest quantity of toxins. It is believed that tabes dorsalis is dependent upon the same form of toxæmia, the part played by syphilis in the pathogenesis of both diseases being essentially that of altering the natural immunity. There is some evidence in favor of the hypothesis that this alteration in the natural immunity is dependent upon commencing exhaustion of the leucoblastic function of the bone-marrow. The treatment of general paralysis and of tabes dorsalis should be directed primarily to the correction of the disorder of the alimentary tract, and probably the only means by which it will be found possible to check the excessive growth of the gastro-intestinal bacteria consists in the employment of a specific antitoxin. To arrest the disease by such means may prove more practicable than would at first sight appear, because it is probable that the specially injurious toxins are the products of only a few bacterial forms.

CO-EXISTENCE OF THE TYPHOID AND MALARIAL INFECTIONS.

THE question as to whether the condition, termed by Woodward in 1862 typho-malarial fever, is a specific disease or is malaria co-existing with typhoid fever has been at intervals since that date a much disputed point. Woodward himself, although he was responsible for the misleading denomination, did not consider that it expressed the affection correctly, for in 1876 at the Medical Congress held that year in Philadelphia, he read a paper in which he distinctly stated that malaria and typhoid fever occurring in the same individual at the same time should not be looked upon as a specific disease, but rather as a coincident infection.

Moreover, the greater number of physicians who have had the opportunity of studying these maladies have passed their opinion to the effect that, when a person is impregnated with the poison of both diseases concurrently, coincident infection is the right word to apply to the state.

Dr. W. G. Thompson, writing of the so-called typho-malarial fever in 1893, said: "The name typho-malarial fever must not be held to imply a specific disease, but rather a combination or co-existence of two diseases, typhoid fever and malarial

fever, in the same person." Osler Thayer, and the French investigators take practically identical views.

The Spanish-American War, during which a large number of soldiers were attacked by typhoid fever accompanied by undeniable symptoms of malaria, aroused renewed interest in the subject, and efforts have been made to settle the matter once and for all. Dr. Irving P. Lyon of Buffalo has set himself to the task and has recently published a pamphlet in which the whole question is intelligently and exhaustively dealt with. He has gathered from various sources, twenty-nine well-authenticated cases, to which he has added one which he himself had charge of in the Johns Hopkins Hospital, and he has reached the conclusion that what is known as typho-malarial fever is actually, as Woodward declared in 1876, coincident typhoid and malarial infection.

Perhaps the portion of Dr. Lyon's paper which will possess the greatest interest to the majority of our readers is his account of the discrepancy in the description of the two-fold infection given by American and French observers. The French writers regard the fever in a far more serious light than do the Americans, asserting that the symptoms are in most instances severe and the mortality correspondingly high, and that rose spots are the rule rather than the exception. The Americans say that the duration of the fever is shorter, and that it is in all respects of a milder type than true typhoid fever and that the occurrence of rose spots is infrequent, while the naturally prognosis is favorable and the mortality quite low. How then to reconcile these diverging views is somewhat difficult.

The explanation given by Dr. Lyon is that a coincident malarial and typhoid infection, as described by French writers, is really in a high degree dangerous to life, for the reason that it is a true infection, but that the typho-malarial fever which is so often adverted to by American writers as prevailing in many parts of the United States, is not in fact the two diseases in conjunction at all, but simply mild typhoid fever or continued malarial fever.

With respect to the clinical picture presented in the cases recorded by Dr. Lyon and in those described by French writers, typhoid fever in nearly all the cases dominated the scene and this would seem to indicate, as Continental observers have suggested, that typhoid fever is the more masterful disease; but as Dr. Lyon wisely points out the important fact must not be forgotten that quinine was freely used against the malarial element whenever it appeared, and in all probability, in some cases at least, completely changed the clinical picture that would otherwise have been seen.

ANIMAL PARASITES IN THE PHILIPPINES.

The Medical Record has persistently urged the establishment by the Government of the United States of a school of tropical medicine. In parts of this country, several diseases met with in the tropics are more or less prevalent, in Porto Rico and Cuba of course still more occur, while the Philippines is a hotbed of a large number of tropical diseases, some of which are obscure and comparatively unknown. A wide field is therefore provided for the pursuit of medical knowledge into which it might be thought that the ruling powers of the United States would be eager to provide facilities for their scientific men to delve. In the meantime Colonel Charles Greenleaf, the Chief Surgeon of our army in the Philippines, has wisely decided that the medical profession of America shall profit if it will by the results of the investigations made by the Army Pathological Laboratory workers in the Philippines, and to this end has ordered to be published a series of medical circulars dealing with the diseases encountered in that island.

These circulars are issued under the direction of First Lieutenant Richard P. Strong, U. S. A., in charge of the Army Pathological Laboratory in Manila. The first number is devoted to a brief consideration of the animal parasites of the Philippines. As Lieutenant Strong modestly says in a short preface the descriptions are given of the parasites as they occur in these islands and sometimes not with the idea of adding anything new, either to their life history, to their anatomical structure, or to their pathological significance. They are recorded in this form because it is hoped they may give some idea to physicians who have lately arrived in the Philippines of the more common intestinal parasites to be encountered there.

Concerning the amœba dysenteriæ the statement is made that of all the intestinal parasites met with in Manila it is the most common and the most fatal in its effects. One hundred and fourteen of 386 deaths among American troops were due to amœbic dysentery, and it disables many more men than any other disease.

Of the infusoria but one variety of the order of Heterotricha has been observed, viz., the Balantidium coli (Stein), Paramecium coli (Malmsten).

Three flagellates have been encountered. Of the tæniæ only two of the adult forms have been observed and no particular investigations have been made in regard to them. Referring to the nematodes, Lieutenant Strong and his co-workers say that, although trichina spiralis is common, no case of trichinosis has come under their notice, and but one case of filariasis. A somewhat lengthy description is given of the ankylostoma duodenale, and it is stated that no confirmation can be accorded the recent statement of Giles that the parasite represents an example of dimorphism or heterogenesis.

Much credit is due to the compilers of the little work, which should prove of value both to army surgeons and to those in civil life. It is also to be hoped that the usefulness of investigating tropical diseases may by these means be impressed upon the Government and that the wisdom of establishing a school of tropical medicine upon a scale commensurate with the resources of the country may be demonstrated.

RENAL TENSION.

It not rarely happens that relief of pre-existing symptoms is afforded by surgical operation, even when the procedure originally intended is not carried out because the condition diagnosticated is not found to exist. No satisfactory explanation has yet been given for this sequence of events, although the influence of suggestion, of manipulation, of exposure to light and air, and of the "operation *per se*," has been invoked to this end. Of course when any direct operative procedure is undertaken

the credit naturally will be given to it, and it must be admitted that an incision into diseased tissue may do good by relieving stasis and engorgement. This essentially is the explanation offered by Mr. Reginald Harrison for the good effects of exploratory puncture or incision of the kidney in the presence of albumin and other renal symptoms suggestive of calculi or other removable conditions, but of which no evidence is discoverable on operation. In a paper on this subject read before the Surgical Section of the British Medical Association at Cheltenham (see page 270), Mr. Harrison expressed the belief that tension of the kidneys may result in destruction of the epithelial lining of the uriniferous tubules, with slow exudation of urine and disorganization, and that when this condition prevails relief may be expected from puncture or incision of either kidney. The indication for this measure is thought to reside in the presence (1) of progressive signs of kidney-deterioration, as shown by the persistence or increase of albumen, when it should be diminishing or disappearing from the urine, as in the natural course of inflammatory disorders ending in resolution; (2) of suppression of urine or an approach to this state; (3) of marked disturbance of the heart and circulatory apparatus in the course of inflammatory renal disorders. The operation consists in exposing the kidney through an incision in the loin and puncturing the organ, or, preferably, making one or more incisions through the capsule of the organ. Drainage is provided for, and the wound is closed and generally heals without difficulty. When both kidneys are affected, operation upon one is usually sufficient for all purposes. The proposition thus briefly outlined seems a radical one, and it is likely that the procedure will be resorted to only when relief cannot be expected from other measures or these have been employed and have failed, unless the kidney is exposed for the relief of some condition that is not found.

News of the Week.

Award of the Nobel Prizes.—Two of the prizes created under the terms of the will of Alfred Nobel, the Swedish engineer and chemist, have been awarded respectively to Dr. Niels Finsen, of Copenhagen, for his discovery of the light treatment for lupus, and to Professor Pavloff, the Russian physiologist, for his researches in metabolism. These prizes, five in number, are awarded annually to those who have done the most "for the benefit of humanity" during the year, and are each one-fifth of the income from an investment of about one million dollars.

A Volunteer for Experimentation with Bovine Tuberculosis.—It is reported from Denver that Mr. T. L. Monson, Colorado State Dairy Commissioner, has offered to submit himself to inoculation with bovine tuberculosis in order to test the question of the communicability of this disease to man. He is said to be a believer in the non-identity of the two forms of tubercle bacilli. If there are many such with the courage of their convictions, the solution of this problem should not be long delayed.

Hay Fever is said to have failed to make its annual appearance on time this year in various parts of the country, and the usual victims and physicians are alike puzzled to account for the delay. Many persons, however, are never attacked until some day in the latter part of August, so that it is still too early for jubilation.

The War on Mosquitos.—Dr. Doty, the Health Officer of the Port, who has been attacking mosquitos in their haunts on Staten Island, has apparently succeeded in materially reducing the number of these insects in the district where the experiment was tried. In this district the inhabitants state there has been a positive change for the better. In several houses lamps are now lighted at night which have not been in use for weeks, and the number of mosquitos has apparently been greatly diminished. No permanent improvement can be looked for, however, as Dr. Doty's operations have been conducted over too narrow an area, and so long as the conditions outside remain as before, there will be little change. The object of the experiment was to demonstrate the feasibility of practically exterminating mosquitos by concerted measures on the part of the sanitary authorities, and this, it is claimed, has been done. Many specimens of anopheles, both larvæ and adult females, were found.

War on Rats in Manila.—An appropriation of $2,500 has been made to meet the expense of a bounty offered by the Manila Board of Health of a cent and a half on every rat killed. This action is taken in the hope of finally stamping out the plague which lurks among the Chinese residents of the city.

Dr. Juan Santos Fernández, of Havana, was the recipient of a gold medal from a number of his colleagues on June 24, his feast day. The medal was given him as a token of appreciation for his labors as President of the Third Pan-American Medical Congress. Dr. Alfonso Betancourt made the speech of presentation, to which Dr. Santos Fernández briefly but feelingly replied.

The Two Oldest Living Alumni of Trinity College are physicians, as we learn from the *Bulletin* for June, 1901, which contains portraits of both. Dr. Gurdon Wadsworth Russell, of the class of 1834, was graduated in medicine from the Yale Medical School in 1837, and lives in Hartford. Dr. Nathaniel Oliver Cornwall, of the class of 1839, was graduated in medicine from the College of Physicians and Surgeons, New York, in 1846. Most of his life has been passed in South America, but his home now is near Portland, Conn.

An Improvement on Christian Science.—Among the natives of the New Hebrides it is the custom, during the prevalence of any epidemic disease, to seek to appease the Divine wrath by strangling the parents of the children and young persons who die. At the present time dysentery exists there, and the mortality from strangling is said to exceed that from the prevailing disease. The treatment there is on the Christian Science order through the incantation of healers or medicine men, which suggests the idea that it might be well always to associate the penalty with this form of treatment. It would no doubt lead to the saving of many lives of innocents now sacrificed to parental fanaticism.

Pay for City Vaccinators.—When the present smallpox visitation first appeared last winter a corps of vaccinators was established by taking forty-five physicians of the school medical staff and appointing them health inspectors. In their former position they received $60 a month, but the pay of a health inspector is $100. The members of the vaccinating corps thus created were paid the larger amount up

to [illegible] Civil Service Commission, objected on the ground that they had passed examinations only for the school staff and were not entitled to the higher salary. The Supreme Court has now decided that the action of the Civil Service Board in refusing to sign the payroll of the forty-five Health Board inspectors, assigned to vaccinate during the smallpox scare, is unconstitutional. All the men have been reappointed at the same salary, $100 per month, and entitled to resume their duties.

Mosquitos in Spanish.—The interesting work on mosquitos by Dr. L. O. Howard is to be translated into Spanish for the benefit of our tropical neighbors.

An Exhibition of Giants was held not long ago in Rouen, France. One of the exhibits, a Frenchman 6 feet 2 inches tall, is to marry another, an English woman measuring 8 feet 3 inches in height.

A Congress of Historical Science is to be held in Rome in the spring of 1902. The committee of arrangements has asked that the Government of the United States send delegates to the congress and invites the participation of American scientists, artists, and men of letters. The congress will discuss all subjects of historical character, including the history of medicine.

Rewards for the Empress's Physicians.—Emperor William of Germany has conferred on Prof. Renvers the title of privy sanitary counsellor and has also bestowed an order on Dr. Spielhagen, who, with Prof. Renvers, attended the dowager empress during her illness. In addition the six ladies-in-waiting of the dead empress have received Red Cross medals.

A Medical Mayor.—Dr. Robert J. Black, the Mayor of McKeesport, Pa., who has recently received a good deal of newspaper notice in connection with the strike of the iron workers, is a physician. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1881.

The Skene Library.—A building for the library donated to Griffin's Corners, N. Y., by the late Dr. A. J. C. Skene of Brooklyn, is to be erected by Mr. Andrew Carnegie. Dr. Skene had planned to have the library suitably housed, but died before such a structure could be built. The building will be called the Skene Library in memory of the donor of the books.

Against the Spitting Nuisance in Paris.—A few days ago thousands of notices were posted on dead walls, houses, boardings, and lampposts in Paris, to the effect that "The public are earnestly requested, in order to avoid the danger of propagating tuberculosis and other zymotic diseases, not to spit in the streets." This notice was issued in accordance with a vote of the municipal council on July 8.

Pure Milk in Chicago.—The health authorities of Chicago have been waging war recently against milk dealers who use formalin as a preservative of milk, information having reached them that this practice was growing very common. The milk is now tested as it arrives at the railway station, and any containing preservatives or of a specific gravity indicating the addition of considerable quantities of water is thrown away.

For the Protection of the Insane. A citizen of New York has offered a reward of $500 for the "conviction of any person ill-treating an insane person in any city institution." This offer is of course well meant, but we believe with *Charities*, that it will accomplish little good, and may tempt some unscrupulous person to false swearing. A much better expenditure of this money, our esteemed contemporary thinks, would be an endeavor to get as superintendent of the Bellevue insane pavilion, where abuse is said to have occurred, some physician experienced in the organization of hospitals for the insane, who if freed from the machinery of city government and given the powers now possessed by superintendents of State hospitals for the insane, "would change this assumed demoniacal stronghold into an abode of content, peace, and harmony."

Veterinarians in the Army.—The veterinary journals are commenting on a picture of a group of veterinary officers of the allied armies in China, showing that those in the armies of England, France, Germany, Italy, and Japan were uniformed officials, component parts of their respective armies, while the American representative was a civilian, not a member of the army.

Smallpox in Middletown.—A number of cases of what seems to be mild smallpox, but of which the diagnosis is somewhat uncertain, are reported from Middletown, N. Y. The disease was brought to the city by two children who were boarding near the city limits. The mother contracted the disease, from which she died. Before death she was removed to a house in the city, and one of the men who assisted in the sick woman's removal, a trained nurse, and a cousin of the dead woman, who assisted in the care of the patient, were all attacked later by the disease. All of the sick are isolated in their respective homes, and every precaution is being taken to prevent a further spread.

The American Association of Obstetricians and Gynæcologists will hold its fourteenth annual meeting at the Hotel Hollenden, Cleveland, Ohio, Tuesday, Wednesday, and Thursday, September 17, 18 and 19, 1901, under the presidency of Dr. William E. B. Davis, of Birmingham, Ala. The committee of arrangements is composed of Dr. M. Rosenwasser, 722 Woodland avenue, and Dr. William H. Humiston, 122 Euclid avenue, Cleveland, either of whom may be addressed concerning rooms or other local information regarding the meeting.

The College of Physicians and Surgeons of Chicago.—The building occupied by this college, the medical department of the University of Illinois, was destroyed by fire, as our readers may remember, on June 25. The work of the college was only temporarily interrupted, and is now proceeding in the new house as smoothly as before.

The Summer Health Corps in Chicago is a volunteer body of twenty physicians who make a regular inspection of the tenement houses of the city, giving instruction and advice to mothers how to keep their babies in good health, and prescribing for the sick children when such are not under the care of any physician. There is also a volunteer corps of nurses who visit the sick whenever requested to do so by the health inspectors.

An International Zoological Congress was held in Berlin during the present week. Among the Americans present were Professors Wilson, of Columbia; MacMurrich, of Michigan; Woodworth, of California; Patton, of Dartmouth; Murrill, of Cornell, and Mark, of Harvard; Dr. Charles W. Stiles, of the Department of Agriculture, and Mr. Leonard Steinger, curator of the National Museum at Washington.

Open-air Treatment for the Tuberculous Insane.—We learn from *Charities* that a system of outdoor treatment for insane tuberculous patients has been in operation in the Manhattan State Hospital for

the last two months. The State Commission in Lunacy reports that it has been attended with gratifying results. Since July 1 about sixty patients have lived and slept in wooden-floored tents on the hospital grounds. As a result many formerly bed-ridden patients are now able to walk and care for themselves.

Mosquitos at Sea.—The surgeons of the Marine Hospital service have reported two instances coming under their notice of ships at sea being invaded by swarms of mosquitos. One of these vessels was the ship *America* which was visited by mosquitos when about ten miles from Chandeleur Island in the Gulf of Mexico. The other was the Spanish bark *Maria Blonquer* which, according to the testimony of the crew, was twenty-two days out from Rio de Janeiro and hundreds of miles from any known land when visited by a great swarm of these insects.

Bequests to Philadelphia Hospitals.—By the will of the late Emily Phillips, of Philadelphia, the following bequests, among others, are made: Jefferson Medical College Hospital, for a free bed in memory of her brother, Henry M. Phillips, $10,000; to the Jewish Hospital, for a ward to be called the Henry M. Phillips Ward, $40,000; Pennsylvania Hospital, $4,000; Philadelphia Hospital for Incurables, $5,000; Montefiore Home for Chronic Invalids, $5,000; Home for Aged and Infirm Hebrews in Philadelphia, $5,000; Medico-Chirurgical Hospital, $1,000; Aged Couples' Home, $1,000; Children's Sanitarium Association, $2,000; Howard Hospital, $1,000.

Obituary Notes.—Dr. CHARLES HAMPDEN FIELD committed suicide in Alameda, Cal., on August 6, by inhaling illuminating gas. He was formerly a surgeon in the United States Army. He was also an ex-surgeon of the Pension Bureau, and at one time surgeon of the Union Pacific Railroad.

Dr. NATHANIEL MOORE JONES of Cleveland, Ohio, died August 1, 1901, of carcinoma of the stomach. He was born in Stowe, Summit county, Ohio, October 5, 1840. At the outbreak of the Rebellion he had been reading medicine in his brother's office for three years, and enlisted in the 115th O. V. I., serving for three years first as a hospital steward, later as Assistant Surgeon. He was graduated from the medical College of Wooster University in 1866, and practised medicine in Cleveland for thirty-five years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THREE CONGRESSES—LONDON, EASTBOURNE, CHELTENHAM—HOSPITAL SUNDAY FUND AWARDS—NATIONAL HOSPITAL—DINNER TO SURGEON-GENERAL JAMESON.

LONDON, August 2, 1901.

THE tuberculosis congress has occupied so much of our attention that other subjects have been put in the shade, though it must be acknowledged that some of our confrères are declaring they have heard enough of Koch and his opponents to last until after a good holiday, and a good number have started. Not a few have gone to Cheltenham for the British Medical Meeting, where the discussion on the reorganization of the association interests a considerable number as much as the work in the sections. I hear, too, that the reception of visitors by "the Garden City," as Cheltenham calls itself, has been as hospitable as possible, and all sorts of social distractions have been provided by the profession there. But your reporters will inform you of what has been done and I leave to them that duty and turn to other subjects.

Another Congress has been sitting during the week—the Royal Institute of Public Health. It is the season for such gatherings. This meeting was held at the pleasant sea-side town of Eastbourne and attracted about 1,000 visitors. The Duke of Devonshire, who is the President, discoursed on the infections against which a health resort should guard itself. They were, he said, indigenous and exotic; as to the former the success of the local authority would be in proportion to its local standing and its means of dealing with infection generally. As to the latter a district was to some extent guarded by superior authorities against foreign diseases, as cholera, plague, etc. The Duke then spoke of protection against smallpox, which, though mainly belonging to local self government, is also to a certain degree undertaken by Imperial authority. He warned his hearers against the neglect of vaccination and told Eastbourne the danger of a health resort becoming ruined by an epidemic of smallpox.

Dr. Newsholme of Brighton presided over one of the sections and urged that the time is ripe for compulsory notification in all cases in which there is reasonable doubt for suspecting infectious disease—a view which, though widely held by sanitarians, does not commend itself to the public. He held that Koch's statement about bovine tuberculosis was premature, and should be investigated under government auspices.

At this Congress Dr. Greenwood of Crewe brought forward the subject of danger in railway carriages, and urged medical legislation to compel disinfection and better cleansing of these vehicles. It was beyond dispute that they often contained tubercle bacilli which, in such enclosed places, retained their virulence for a long time. Persons predisposed to phthisis ran great risk in entering such carriages, and the danger was greater when the windows were kept shut. A resolution was adopted calling attention of the government to the danger caused by lack of frequent wet cleansing and disinfecting of railway carriages, tramcars, and omnibuses.

Other papers dealt with the hygiene of elementary schools, education on health subjects, the late epidemic of plague in Glasgow, and the housing of the poor.

The Council of the Hospital Sunday Fund met on Tuesday under the presidency of the Lord Mayor, when £44,534 were distributed. The collection this year had reached only £51,000, so that the ambition of the Council to reach £100,000 is hardly likely to be attained for some years. It was proposed to withhold the award to the National Hospital for Paralysis and Epilepsy until complete harmony had been restored between the staff and the Board. But an outcry was raised by its friends, and the Council gave way and agreed to pay last and this years' grant, but to defer future payments in the event of further disagreements cropping up. A plea for another institution was equally successful, showing that the Council can swallow its convictions when influential persons speak, although it suffers its officials to repudiate the claims of smaller institutions.

The dinner to Surgeon-General Jameson, C. B., late Director General of the Army Medical Department, was the occasion of considerable enthusiasm, and must have been gratifying to this distinguished officer. The dinner may be regarded as a protest against the government, which allowed General Jameson to retire without a word of thanks or acknowledgment for his services—still less the honor usually conferred. Sir W. McCormac again testified that the department had worked well, and he mentioned that at the present time not a single candidate is applying for admission into the Medical Service. The blame of other departments has been shifted on to the medical, which has done better than any; the ex-director foresaw and provided against the contingencies that took place, but his plans were frustrated by others.

NOTES ON SOME OF THE MEDICAL FEATURES OF THE PAN-AMERICAN EXPOSITION.

THE EMERGENCY HOSPITAL—THE INCUBATORS—THE CRÈCHE—DEFECTIVE VENTILATION IN THE ART GALLERY—THE ARMY MEDICAL EXHIBIT—THE MARINE-HOSPITAL SERVICE.

(Special Correspondence of THE MEDICAL RECORD.)

THERE is much in the Exposition at Buffalo to attract and hold the attention of scientific and medical men. A person desirous of viewing thoroughly and of studying with some care the numerous exhibits exemplifying progress in medicine and science, will not only need to have a considerable amount of time at his disposal, but will also find his task greatly facilitated if he has a knowledge of the location of the features of interest.

Upon entering the West Amherst Gate the first building that strikes the view is the Emergency Hospital, the general plan and functions of which were described at length in the MEDICAL RECORD some three months ago. It may nevertheless be mentioned that its province is

wholly restricted to emergency work, that serious cases are transferred to institutions outside the grounds, and that no patient is permitted to remain overnight. The building contains twenty-six beds, and is excellently equipped in accordance with the latest methods of sanitary science. The medical director of the Exposition, Dr. Roswell Park, looks after its administration and, with Dr. Vertney Kenerson, the physician directly in charge, visits the institution daily. The house staff is composed of six young medical men who take duty in turn, two at the same time. The nursing staff comprises four nurses. There is also in the service of the hospital an automobile ambulance in charge of medical students of the University of Buffalo.

The hospital during the three months of the Exposition's existence has treated upwards of 3,000 cases, the majority of which have been medical. It is satisfactory to note that there have been but few cases of a grave nature and that the occurrence of sunstroke and heat exhaustion has been remarkably rare. This fact, when taking into consideration the prevalence of excessive heat all over the country at the end of June and at the beginning of July is decidedly noteworthy, and says volumes for the salubrity of Buffalo.

By far the larger number of those who have made use of the hospital up to the present time have been women, while among the employees and temporary residents of the Exposition the foreign element has supplied the bulk of the patients. The complaints have been characterized for the most part by their simple nature, and there has been no suspicion of anything resembling an epidemic. Probably the diarrhœa and stomach disturbances to which the foreigners have shown themselves especially prone, may be attributed to an unaccustomed mode of living, and perhaps to injudicious eating and drinking. On the whole, however, the health of the Exposition inhabitants has been highly satisfactory, as has been also the health of the visitors to the great fair.

Those who are responsible for the management and supervision of the Emergency Hospital must be commended for the admirable manner in which their duties have been carried out, and they can lay the flattering unction to their hearts that their work has been well appreciated by the general public.

The incubation of infants seems, to use an every-day colloquial expression, to have "caught on" in more than one sense of the word. The method, of course, is largely resorted to for the rearing of weakly infants, and it also would appear to be equally popular from an exhibition standpoint.

In London, some few years ago, an exhibition of infants in incubators was an adjunct to Barnum's show, and at that time the *Lancet* passed severe strictures upon the procedure, declaring that the scheme was deserving of grave censure, and that it was neither fitting nor right that hapless babes should be placed on exhibition for the sake of gain. While one may agree with the remarks of our contemporary so far as this side of the question is concerned, it nevertheless cannot be denied that incubators have been the means of saving the life of many a prematurely born infant—whether for its weal or woe is altogether another matter. As, however, it seems that incubators have come to stay, the object should certainly be to provide the very best of the kind. The invention of and improvements made in the couveuse have been dealt with fully at different times in the MEDICAL RECORD.

The incubators, twelve in number, are placed around a well-lighted room of which the walls and floors are impermeable. The incubators are glass-covered, and the infant reposes upon a mattress of woven wire, padded with soft material. A card is placed above each incubator, stating the date of the occupant's birth, its weight, and other details. A uniform temperature is assured in the incubators by means of a thermostat. The heat is derived from a metal boiler, which can be heated by a Bunsen burner or by an ordinary lamp. Ventilation is provided by the introduction of fresh air into the incubator from outside, the air being sterilized by filtration through an antiseptic fluid and then through cotton. The infants are taken out of the incubator every two hours and removed to a small room fitted as a nursery, there being fed by wet nurses and inspected as to their condition of cleanliness.

Nearly all the infants on exhibition are stated to be seven months children. Whatever may be thought of the incubation method of preserving life, it must be confessed that the exhibition at Buffalo is excellently conducted, and is one of the most popular of the entire exposition. Indeed it is quite amusing to watch the crowds that frequent the baby show, which but goes to prove that after all a spectacle of human interest is most attractive to all classes.

On one side of the Emergency Hospital a "crèche" has been established, the lack of such a necessary haven of rest for weary little ones having been greatly felt, its institution was largely due to the eloquent plea on behalf of tired mothers and children set forth recently in the *Essex Medical and Surgical Journal*. The crèche will be undoubtedly welcomed with lively feelings of gratitude, and will not only be highly appreciated by mothers of small families, but will be the means of bringing to the exposition many parents with their quivers full who would otherwise be compelled to forego a visit.

A few words may be said in regard to the sanitation of the Exposition as a whole. The buildings are almost without exception well constructed, and due attention has been paid to their ventilation and hygienic qualities generally. There is, however, one conspicuous and even glaring exception to this satisfactory state of affairs, and this too in a building which contains one of the most attractive and popular displays on the grounds, and which is largely frequented by visitors to the Exposition. The ventilation and sanitary arrangements of the art galleries, are, to put the case mildly, extremely defective. When the weather is warm, the atmosphere of the interior of the structure devoted to the fine arts is oppressive to a degree, and judging from the odor which commonly prevails, there must be something very wrong with the plan upon which the sanitation has been conceived. Even an enthusiast in art, and one who is carried away by his love for the beautiful, is nevertheless, rarely so unconscious of sublunary matters as to be unwitting of heat and altogether careless of an offence to his olfactory organs; while to the ordinary individual the discomforts of the art building are apt to outweigh the pleasure of gazing upon the really fine specimens of the artist's and sculptor's craft contained therein.

Perhaps the most instructive and interesting display in the entire Exposition—at any rate to the medical man—is that made by the medical department of the army. This exhibit, which is under the direction of Captain Edward L. Munson, of the United States Army Medical Department, is the largest and most complete of any in the exposition, and represents a model brigade field hospital, exemplifying its equipment and working down to the smallest detail. The only drawback to the unqualified success of this practical presentation of army medical methods is that the space allotted is decidedly limited in extent. So that, although the brigade field hospital is in itself illustrative of its object, the drill of the Hospital Corps has to be considerably curtailed owing to inadequacy of area.

The tents constituting the brigade field hospital are pitched in close proximity to the main Government Buildings, and are arranged in form of a cross, the medical and surgical tents, mess kitchen, and office tents being placed within the arms of the cross, a position shown by experience to be the most convenient as well as calling for the least amount of time and energy. One hundred beds are provided in the hospital for a brigade numbering 5,375 war strength; a proportion of two per cent. sick can thus be cared for.

The tents used are those invented by Captain Munson, and it is claimed for them that their ventilation is effective, and that the temperature of the interior is, in tropical climates, materially lowered. The test to which these tents have been put in Cuba and the Philippines is stated to have justified the encomiums passed upon them. The exhibit at Buffalo is the first that has been publicly given of the improved methods now in vogue in the U. S. Army Medical Department. The revised system is the outcome of the careful and prolonged deliberations of a board of medical officers, who made a painstaking study of army medical arrangements of the principal countries of the world, by personal observation or by correspondence. Any features worthy of adoption were embodied into the American system, the weak spots were eliminated or improved upon, and the assertion is now confidently made that no nation of the world can equal or even approach the Army Medical Department of this country as regards its organization and more especially its equipment. Economy of space and reduction of weight of material has been the watchword, and this result has been reached not only without detriment to the health or comfort of the soldier, but rather to his advantage. The lesson learned in the war with Spain has been fully utilized, and drugs in sufficient varieties and quantities to last a field brigade at war strength, under active service conditions for ninety days, are carried with the dispensary tents of the hospital. Space is lacking to describe at length the many ingenious devices resorted to, for the purpose of packing within a small compass, and thereby rendering transportation easier. It will suffice to point to the new model medical chest as a striking example. This chest, while weighing but eighty pounds, or thereabouts, contains drugs and medical supplies enough to last in the ordinary way 1,600 men for ninety days. Three field chests—medical and

surgical and sterilizer—form a regimental set, which can be carried by one man, two by two men on a litter, and three constitute a mule load. The same judgment has been displayed to render transportation as easy as possible in the mode of packing the hospital furniture. Each table in a tent can be quickly transformed into an operating table, and, with the chairs, can be taken to pieces and placed in a small chest. The bedding and other impedimenta of a hospital tent are contained in a canvas bag. In fact, a type even in army medical matters cannot fail to be impressed with the ingeniously simple devices which exist out and put into practice for the behoof of the sick, and to enable a field hospital to keep in touch with the troops on the march, and thus permit the Army Medical Department to perform its duties efficiently. The army hospital corps give twice in the day, on a plot of ground adjoining the brigade field hospital, a smartly-executed exhibition of an emergency drill. The army medical exhibit is quite one of the most popular features of the exhibits in, and is daily thronged by a crowd of the interested and curious.

In the main Government Building the U. S. Marine-Hospital Service has a comparatively small but symmetrically complete exhibit, illustrating in an effective manner the methods and material of the service.

The exhibits are under the charge of Mr. Samuel W. Richardson, hospital steward, whose duties for many years have been rather of an executive nature than those appertaining to the rank of steward.

Models are shown of quarantine stations and detention camps; models of a section of a ward and of a marine-hospital operating room; a Kinyoun-Francis vacuum chamber as used at quarantine stations for disinfection of clothing; a complete X-ray outfit; a traveling laboratory. This latter is an eminently useful and, indeed, under certain circumstances, an essential part of the service's equipment. It may be easily understood that at times specimens for bacteriological investigation or for chemical analysis must be examined at once, as many would spoil during transportation to the Hygienic Laboratory at Washington. Therefore, a traveling laboratory, furnished for making immediate bacteriological examinations and chemical analyses, such as used by the Marine-Hospital Service, may be said to be a necessary adjunct to its outfit.

Another feature of this exhibit which is deserving of special mention is the system of clinical reports devised by Surgeon-General Wyman. Clinical record sheets are issued for the use of the ward physician, upon which he writes in the usual way a history of the case, treatment, diet, etc. The point, however, to which it is wished to draw particular attention is that upon the discharge or death of the patient, these sheets, together with the temperature chart, are bound in a paper cover, upon the outside of which are inscribed the name, malady, and age of the patient, with other facts bearing on the case. The reports, thus bound, are then arranged in cabinets, under the head of the disease from which the patient suffered, and, further, in another part of the cabinets, the case is tabulated under the name of the patient. The merits of this system are obvious, as prompt reference can be had to the history of any case. It would be superfluous here to touch upon the excellent work done in the past by the Marine-Hospital Service. The exhibits at the Buffalo Exposition are, however, a remarkably convincing evidence that it is the object of the service to retain and add to a well-earned reputation, and with this end in view, to spare neither brains nor time in improving the organization and equipment and in taking any steps which would seem to tend to the perfecting of the establishment.

THE PRE-OPERATIVE DIAGNOSIS OF "TUBAL ABORTION" AS DISTINGUISHED FROM ACTUAL RUPTURE OF AN ECTOPIC TUBE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Permit me to ask for a little of your valuable space for a short but important correction.

In a recent issue, under the report of the Section on Obstetrics and Gynæcology of the Academy of Medicine, at a stated meeting held May 23, 1901, your reporter says, "Dr. Paul F. Mundé presented specimens from two cases of ectopic pregnancy, one of them a tubal abortion. Because of the *sudden sharp pain and rapid collapse* and the symptoms of *gradual internal hemorrhage* (italics mine) he had been able to make the diagnosis of tubal abortion in this instance before operating." Your reporter should have said, as I stated at the time, "because of the *absence* of sudden sharp pain and rapid collapse, etc.," for the absence of these symptoms, together with the evidence of gradual, slow, persistent internal hemorrhage, as shown by the steadily increasing general anæmia, are the characteristic signs of tubal abortion as distinguished from the sharp, acute pains and sudden alarming collapse peculiar to the rupture of a similar ectopic tube at some point between its uterine and abdominal orifices. I understand this distinction clearly; I may, perhaps, be allowed to say that a tubal abortion is the gradual detachment of an impregnated ovum from its faulty location in the ampulla of the tube close to its abdominal orifice; there is no rupture of the tubal calibre, but merely a tearing loose of the ovular attachments, which process, as in ordinary uterine abortions is attended by bleeding, often merely oozing, and is devoid of any particular pain. This condition usually attracts attention through the gradually increasing general anæmia, and the pressure and weight in the pelvis, and especially on the rectum, as the amount of effused blood increases and the coagula become firmer. I have seen such a tubal abortion continue for three weeks, the pelvic tumor gradually growing from the size of a hickory nut to that of a cocoanut, and the anæmia steadily increasing without pain or urgent symptoms until it was thought justifiable to open the abdomen, and the suspected diagnosis of ruptured ectopic pregnancy was confirmed and amended by the discovery that the case was really a tubal abortion. The practical importance of making an early even if diagnosis of tubal abortion, as distinguished from the rupture of an ectopic tube, is evident from a clinical standpoint—for the ruptured tube is a far more serious and urgent condition—as well as on surgical grounds, since, while both require operation in the large majority of instances, the tubal abortion may often wait, whereas the ruptured tube usually demands its immediate removal. There is one more point, and that is, that an ectopic tube may rupture into the peritoneal cavity or between the layers of the broad ligament, in which latter case the effused blood can be evacuated through an extraperitoneal vaginal incision, and a speedy cure effected, or if comparatively small in quantity may be absorbed, and an operation avoided; whereas the hemorrhage from a tubal abortion is always intraperitoneal, and unless very trifling, invariably calls for an abdominal or vaginal section and the removal of both tube and coagula.

PAUL F. MUNDÉ

SOUTHAMPTON, L. I., July 29, 1901.

Progress of Medical Science.

Journal American Medical Association, August 10, 1901

Primary Carcinoma of the Nasopharynx.—Chevalier Jackson gives a table of 14 cases. The points which he suggests for discussion are the following: 1. Why is carcinoma of the nasopharynx relatively so rare? 2. Has the relative infrequency of carcinoma of the nasopharynx any bearing on the subject of irritation in the etiology of cancer? 3. Is a radical operation ever justifiable in undoubted carcinoma of the nasopharynx? 4. If justifiable in the very early stages, at what stage does a radical operation become unjustifiable? 5. If a radical operation be unjustifiable, what can we do to make the termination euthanasia, not cacothanasia?

Case of Nasal Sarcoma.—Dunbar Roy reports a case in which the cutting off of the blood supply by ligating the external carotids was tried, but without lasting benefit, as the patient died seven months after the appearance of the first symptoms. The tumor began as a stopping up of the nasal cavity. The symptoms of severe bleeding whenever any growth within the nasal cavities is touched should make us suspicious, says the author, and such should be removed early in the most radical way possible. He is opposed to curetting, for it offers a chance of turning benignant into malignant growths, if such a thing is possible. Toxins are effective by destroying the growth, but in the case reported their use was not persisted in, for the resulting disfigurement would have been worse than death.

Report of a Case of "Epithelioma" Involving Tonsil, Faucial Pillar, Tongue, and Buccal Surface, with Treatment and Apparent Cure.—S. A. Oren reports a case diagnosed as epithelioma by the Columbus Medical Laboratory of Chicago. Specific treatment was given internally on general principles, and externally sprays of various solutions were employed. Oftentimes the trouble seemed under control, and then would apparently spread. Cox-comb growths were snipped off and the base was cauterized. Hypodermic injections of pure alcohol were made in several places outside of the periphery of the ulcer and in and above the anterior faucial pillar. The resulting inflammation soon subsided, leaving a circumscribed hard mass. This, after the injection of suprarenal extract and cocain, was dissected out, the base of the wound being curetted and cauterized. The patient was apparently cured, and for a year has had no return of symptoms. The author urges hopefulness and patient treatment in these apparently hopeless cases.

The New York Medical Journal, August 10, 1901.

Suggestion for a Study of Fats in Their Relation to Physiological Chemistry, Therapeutics, and Toxicology.—John Reid thus sums up his views: 1, In urinary analysis, oleic acid is useful and speedy in dissolving various principles; 2, in analyzing organs, they may be partly analyzed by acidulating and extracting with supernatant oleic acid, or the fat should be skimmed off and treated with benzine, so as to make complete the analysis. 3, fat may be used to eliminate poisons from the body. 4, the elective affinity of drugs may be partly due to their fat affinity; 5, the whole subject of fat in its relation to the economy is worthy of careful study.

The Home Treatment of Tuberculosis.—Irwin H. Hance mentions the following points as the essentials in home treatment (*i. e.*, care of the patient in some near-by country place where the environment is changed but climatic conditions remain the same). *Fresh air*, every day and every night, the more the better. *Food*—over-feeding must be the rule; food alone improves nutrition and produces increased powers of resistance. This is nature's sole means of eluding the excursions of the disease, diminishing its powers for evil, and producing a condition of arrest which neither medicines nor serums have as yet been capable of doing. *Rest* should be absolute in febrile cases and in all cases at the commencement of treatment for from one to four weeks. The physician must carefully watch the effects of exercise as to temperature, heart's action, chills, blood in the sputum, weight, and over-fatigue. The care of the skin is very important. Directions for bathing are given.

Cleft Palate and Its Association with Hare-Lip.—John H. Branth says in reference to the hare-lip operation, that the law to sacrifice as little as possible holds good here as in palate operations. A simple notch, where the floor of the nostril is not involved, can be remedied by a simple inverted V-incision above the vermilion border; the inner V is pulled down, and the lateral angles are brought together by stitches; the now lower portion *must* be pendent, to allow for cicatricial contraction, or the result will be a small notch. Where the labial fissures extend into the nostril, as occurs in complete cleft, we have left, after the successful palate operation, either a single or a double hare-lip. The problem is to build a floor for the anterior nostril. This is best achieved by Colles' (of Dublin) so-called æsthetic operation. The cuts are so made as to join the fibres of the orbicularis oris firmly and, by the writer's modification *without angles;* the incisions will fall in the line of the infranasal columns, which are in fœtal life the lines of union. Cicatrices here will look like normal facial lines, and in later life cannot be defined as surgical scars.

Philadelphia Medical Journal, August 10, 1901.

Report of a Case of Raynaud's Disease.—Benjamin F. Lyle and John E. Greiwe present a case of Raynaud's disease with fatal termination, with a detailed pathological report. The conclusions are that there are two classes of cases; those in which the exciting cause acts temporarily and in which the symptoms disappear with the cessation of the cause, and those cases in which the cause acts upon the peripheral vessels causing changes in their calibre by endothelial proliferation. It is fair to consider that the disease may show besides lesions of the extremities, series changes in the internal organs.

The Bucco-Antral Route in Neurectomy for the Relief of Tic Douloureux.—Gordon King advocates the Fraenkel method for neurectomy of the second branch of the trigeminus in obstinate neuralgia. In two cases in his own practice he operated by this method, slightly modified in that after incision he elevated the periosteum as high as the infraorbital foramen, divided the nerve at this point and opened the entire canal into the antrum, simplifying the original procedure, allowing the resection of a greater length of nerve and insuring complete closure of the wound by dispensing with the gauze drain. He removed the nerve by twisting and avulsion. He favors extracranial resection of the nerve trunks in obstinate trifacial neuralgias before the dangerous operations are attempted.

A Case of Tic Douloureux with Successful Removal of the Gasserian Ganglion. Henry T. Williams reports a case of trifacial neuralgia in a woman thirty-eight years old, which had lasted with intermissions, for ten years. She had undergone, without permanent relief, division of the nerves on the right side of the face, extraction of all the teeth, removal of the superior maxillary ganglion, trephining of the inferior maxillary bone, and finally became such a sufferer that she could not sleep without anodynes, and could only with difficulty eat soft food. At the final operation the Gasserian ganglion was removed, and about a quarter of an inch of the superior and inferior maxillary divisions of the trifacial was resected. The Gasserian fissure was also scraped. Primary union occurred, the patient being discharged well in eighteen days. She was free from pain, could open her mouth wide, and four days after operation could eat solid food. Several months later she was well and without pain.

American Medicine, August 10, 1901.

Hay Fever in Mid-ocean.—W. C. Hollopeter reports a case of hay fever occurring in mid-ocean. He offers as a possible explanation that there may have been some articles in the individual's cabin that had not been disturbed since his attack of the year before, and that the use of some of these objects, books, etc., may have provoked the respiratory irritation.

Acute Dilatation of the Stomach.—Julius Friedenwald reviews the literature of this subject, dividing the cases into two varieties—those due to sudden overloading of the stomach or gross dietary error, and those due to muscular paralysis of the stomach of central origin. He reports two cases of the first variety in his own practice. He thinks it advisable to consider the possible occurrence of acute dilatation in all cases of acute dyspepsia and to empty the stomach quickly to avoid such a contingency.

Medical News, August 10, 1901.

Gouty Affections of the Kidneys.—Richard K. Macalester states that in all cases of gout as well as lithæmia in which he has made quantitative analyses of the urine, there was without exception a marked diminution of the daily amount of urea excreted independent of any evidence, chemical or microscopic, of coexisting renal lesion. The relative etiology of gout and kidney disease is still a matter of controversy. His results in the treatment of these affections by mineral-water baths have been encouraging.

The Therapeutics of Subacute and Chronic Heart Diseases.—Thomas E. Satterthwaite indicates the following changes in modern therapy of subacute and chronic heart diseases: The treatment by complete rest has given way to rest alternating with activity; venesection has been replaced by determination of the blood to the surface through resistant exercises and carbonated baths; hydragogue cathartics, by stomachics, mild laxatives, and diuretics; heart stimulants, by general nerve stimulants or sedatives and nutrients, while the digitalis group is used chiefly for diuretic action in renal complications. Drugs of the digitalis group, including strophanthus, convallaria, and adonis are uncertain, therefore dangerous, and should only be employed when other remedies are inadvisable, in renal or hepatic complications, or when the object is merely to prolong life.

The Condition of the Kidneys with Reference to the Employment of Diuretics.—Arthur R. Elliott concludes that diuretics, with the exception of the irritant-epithelial class, affect the urine indirectly through the circulation, and that the secretory diuretics are contraindicated in irritative and inflammatory renal conditions. Simple diluents and salines are best adapted to functional urinary disorders, as the main object is to overcome concentration and hyperacidity of the urine. In acute nephritis, saline diuretics exert a beneficial influence by increasing elimination; the most powerful eliminant is subcutaneous saline infusion. In chronic nephritis the cardiovascular diuretics are the most useful, the symptoms being usually the result of circulatory failure. Dropsy of purely renal origin is not favorably influenced by diuretics. The condition of the heart and circulatory apparatus in most cases of morbid renal conditions determines the choice of a diuretic.

Uræmia and Its Differential Diagnosis.—S. D. Hopkins differentiates uræmia from cerebral hemorrhage by the presence in the latter of constant hemiplegia, conjugate deviation of the eyes, and pupillary inequality; from unilateral convulsions of cerebral disease by the seat of convulsions being constant; from simple syncope by absence of muscular rigidity, paralysis, and retinal change; in chloral poisoning there is no muscular twitching; alcoholic coma is always noisy; in lead poisoning, lead is present in the urine, and there is the characteristic blue line; in diabetes mellitus the sugar in the urine points to the diagnosis; in epileptic coma when the previous history is not obtained, absence of albumin and casts in the urine and of retinal degenerative changes would be differential points. Convulsions or coma of dementia, chronic alcoholism, and syphilis can be detected by symptoms pointing to organic brain disease.

The Boston Medical and Surgical Journal, August 8, 1901.

Intracranial Pressure after Head Injuries.—Walter B. Cannon concludes, from the results of experimentation,

that injuries to the brain interfere with its proper blood supply. Such interference causes an increased osmotic pressure within the tissues, and a consequent taking up of water from the surrounding plasma. The swelling and œdema of the brain after head injuries, therefore, are not due to passive transudation, but are the result of an active process in the tissues themselves, a force many times greater than blood pressure, and amply sufficient to produce all the pressure symptoms and account for all the signs of intracranial tension which the clinical cases of cerebral trauma often manifest.

The Relation of Bodily Mutilations to Longevity.—John Homans, writing from the standpoint of life insurance, says that injuries to the skull, with loss of substance, prevent the applicant from being a good risk; without loss of substance, and with no symptoms, he would be as good a risk as any one. Loss of sight from injury is no bar, but those whose eyes have been removed for carcinomatous or sarcomatous growth are usually short lived. Loss of limbs is apt to induce mental depression and a resort to alcohol and morphine. Persons whose stomach, spleen, liver, or kidneys have been interfered with surgically or by accident do not promise a longevity which would justify their insurance. Those who have suffered removal of a small portion of the intestines for injuries or gangrenous hernia, or of the appendix, have a good chance of living to be old. Women who have had ovariotomy or hysterectomy performed are not apt to be so long-lived as the healthy. After hysterectomy performed for fibroid tumors, however, the probability of longevity is good. By careful selection many mutilated persons might be picked out who would be good subjects for life insurance.

The Relation of Alcoholism to Tuberculosis.—T. N. Kelynack says that three views of this subject are possible: (1) That alcoholism is antagonistic to tuberculosis; (2) that alcoholism bears no special relationship to tuberculosis; and (3) that alcoholism definitely predisposes to tuberculosis. The author reviews the opinion of various authorities in regard to these three views. In his own hospital work he has for years analyzed and observed cases bearing on this subject. Eight fatal cases of peripheral neuritis occurring in alcoholics were subjected to pathological examination, and pulmonary tuberculosis was found in seven. In the recent outbreak of arsenical neuritis in Manchester, which occurred principally in alcoholics among the poorer classes, in many of the fatal cases there was pulmonary tuberculosis. Tuberculosis is also of frequent occurrence in the subjects of alcoholic cirrhosis of the liver. Out of 121 cases of common cirrhosis, tuberculosis was present in twenty-eight.
